The main function of the mitotic spindle is to successfully distribute the genetic material packed on chromosomes to the two daughter cells during cell division. This essential function can be divided into two crucial steps: chromosome congression (Figure 1), which defines prometaphase and metaphase mitotic stages, and chromosome segregation (Figure 2), which defines anaphase and telophase.

Chromosome Congression

After nuclear envelope breakdown at the onset of mitosis, a large number of microtubules originate from the centrosomes, and, together with chromokinesins, generate PEFs that help chromosomes to arrange in a toroid conformation on the spindle surface. Chromosome arms become oriented away from the spindle, protecting their kinetochores from being shielded by other chromosomes and making them more reachable by growing microtubules from both spindle poles (Magidson *et al.*, 2011). Chromosomes that are initially situated much closer to one pole relative to the other have less chance to be reached from both spindle poles, and their congression is facilitated by the motor proteins Dynein and CENP-E (Barisic *et al.*, 2014; Figure 1(a)). Kinetochores of these chromosomes first become laterally attached by centrosomal microtubules and then are transported closer to the pole by the minus end-directed action of Dynein (Rieder and Alexander, 1990; Li *et al.*, 2007; Vorozhko *et al.*, 2008; Yang

Figure 1 Mechanisms of chromosome congression. (a) Initial positioning of chromosomes after the nuclear envelope breakdown affects chromosome congression. Peripheral chromosomes that are initially closer to one pole than the other (P) depend more on motor proteins to congress to the metaphase plate than the centrally localized chromosomes (C), which can easily be reached from both poles. (b) Centrally localized chromosomes then become bi-oriented and align via changes in microtubule polymerization dynamics, while peripheral chromosomes are carried to the spindle poles by motor activity of Dynein. (c) After reaching the pole chromosomes continue to congress towards the metaphase plate mainly via activity of another motor protein – CENP-E. (d) Coordination of different motor protein activities and microtubule dynamics results in successful alignment of all chromosomes at the mitotic spindle equator in metaphase. Micrographs of fixed and live samples represent parental and H2B-GFP/mCherry- α -tubulin expressing U2OS cells, respectively. In the micrographs of fixed cells, chromosomes are labeled in blue (DAPI), kinetochores in red (ACA), and microtubules in green (mouse anti- α -tubulin antibody); the similar color code as used in the figure. Scale bar: 5 μ m.

et al., 2007b; Figure 1(b)), whereas the chromosomes that are initially positioned between the two poles quickly biorient, stabilizing end-on kinetochore microtubule attachment via the KMN network (Cheeseman and Desai, 2008). Thus, Dynein exerts the dominant force required for congression of peripheral chromosomes, overcoming the activities of CENP-E and chromokinesins and preventing the establishment of premature

end-on kinetochore microtubule attachments (Barisic *et al.*, 2014). Once at the pole, CENP-E becomes the dominant force, promoting chromosome congression to the metaphase plate (Kapoor *et al.*, 2006; Figures 1(c) and 1(d)). At the equator, chromokinesins are required to maintain chromosome alignment, possibly by stabilizing end-on kinetochore microtubule attachments (Wandke *et al.*, 2012; Cane *et al.*, 2013).

Figure 2 Mechanisms of chromosome segregation. (a) Once the last chromosome becomes bi-oriented and aligned, the cell is ready to enter anaphase. Spindle assembly checkpoint (SAC) is now satisfied, resulting in the activation of anaphase-promoting complex/cyclosome (APC/C) and consequent drop in CDK1 kinase activity and resolution of sister chromatid cohesion. (b) Chromosome separation in anaphase A starts with the shortening of kinetochore microtubules that is driven by microtubule depolymerases and poleward flux. (c) In anaphase B sister chromatids further separate due to spindle elongation caused by motor protein-driven microtubule sliding. (d) Finally, the chromatids decondense, and a cleavage furrow is formed by contraction of actin–myosin ring, surrounding the central spindle and preparing the cell for the abscission in cytokinesis. Micrographs of fixed and live samples represent parental and H2B-GFP/mCherry- α -tubulin expressing U2OS cells, respectively. In the micrographs of fixed cells, chromosomes are labeled in blue (DAPI), kinetochores in red (ACA), and microtubules in green (mouse anti- α -tubulin antibody); the similar color code as used in the figure. Scale bar: 5 μ m.

The transition from lateral to end-on attachments depends on several pathways. The localization of the dynein motor complex to the outer kinetochore layer is very dynamic and depends on Spindly, which is loaded on kinetochores through interaction with the RZZ complex (Rod-ZW10-Zwilch) (reviewed in Barisic and Geley, 2011). Apparently, the role of the RZZ complex is to support lateral contacts by decreasing the

binding affinity of the Ndc80 complex for microtubules, which is regulated by Spindly and Dynein. When Dynein removes this whole complex through its poleward motor activity, the inhibition of Ndc80 is relieved, allowing the formation of stable end-on attachments (Barisic *et al.*, 2010; Gassmann *et al.*, 2010; Cheerambathur *et al.*, 2013). A recent study also proposed roles for CENP-E and MCAK in lateral to end-on

attachment conversion (Shrestha and Draviam, 2013). Accordingly, while CENP-E is required to tether the kinetochore to the microtubule lattice, MCAK resolves these interactions in a subsequent conversion step. In addition to these two pathways, it was also shown that Bub1, a spindle assembly checkpoint kinase (Meraldi and Sorger, 2005), as well as the astrin/SKAP complex (Dunsch *et al.*, 2011), play an important role in this transition.

Kinetochore-driven formation of microtubules may additionally promote chromosome congression and biorientation, since these microtubules extend toward the poles and can become captured by growing astral microtubules and incorporated into the bipolar spindle in a Dynein-dependent manner (Maiato *et al.*, 2004a; Elting *et al.*, 2014; Khodjakov *et al.*, 2003).

Error Correction

Once stably attached, the kinetochore attachment site must be robust enough to resist the forces applied by spindle microtubules. However, before stabilization, kinetochore microtubule attachments must be rapidly reversible to allow for correction of errors (Cheeseman and Desai, 2008). Indeed, during early mitosis, erroneous attachments happen frequently, for instance, when both kinetochores are connected to the same spindle pole (syntelic attachment). Merotelic attachments may also arise when one kinetochore is attached to both spindle poles simultaneously. This type of aberrant attachment is particularly dangerous, because it cannot be detected by the spindle assembly checkpoint (discussed in more detail below). In contrast to merotelic attachments, syntelic attachments are highly unstable and are corrected before biorientation is achieved. Failure to correct these attachments may result in chromosome segregation errors, giving rise to aneuploidy, a hallmark of many cancers.

Error correction is carried out mainly through the activity of Aurora B kinase. When the activity of this kinase was disrupted by small-molecule inhibitors, the frequencies of both merotelic and syntelic errors increased significantly (Hauf *et al.*, 2003; Ditchfield *et al.*, 2003; Cimini *et al.*, 2006). Moreover, error correction requires active Aurora B kinase (Lampson *et al.*, 2004). Aurora B kinase phosphorylates several microtubule depolymerases, such as MCAK and Kif2B (Andrews *et al.*, 2004; Bakhoun *et al.*, 2009; Lan *et al.*, 2004), as well as proteins required for the stabilization of end-on kinetochore microtubule attachments, such as Ndc80 (DeLuca *et al.*, 2006; Cheeseman *et al.*, 2006; Ciferri *et al.*, 2008).

Aurora B localizes to the inner centromere between two sister kinetochores. Upon chromosome biorientation, tension is applied along the centromeric region, resulting in increased distances between the sister kinetochores, as well as alterations in kinetochore architecture (reviewed in Maresca and Salmon, 2010). This leads to physical separation of Aurora B from the Ndc80 complex, causing its dephosphorylation and increasing kinetochore affinity for microtubules (Fuller *et al.*, 2008; Liu *et al.*, 2009).

Finally, Aurora B activity is counteracted by protein phosphatase 1 (PP1), localized at the outer kinetochore plate, causing dephosphorylation of Aurora B substrates at the

kinetochore (Emanuele *et al.*, 2008; Francisco *et al.*, 1994; Liu *et al.*, 2010).

Chromosome Separation

After completing the biorientation of chromosomes, cells can proceed to the next step of cell division, anaphase. The initiation of this step is under the control of the spindle assembly checkpoint (SAC), which monitors kinetochore microtubule attachments (Khodjakov and Pines, 2010). The SAC inhibits the anaphase-promoting complex/cyclosome (APC/C), a ubiquitin ligase that targets proteins for degradation by the proteasome (reviewed in Musacchio, 2011). Two main APC/C targets are Cyclin B and Securin. Degradation of Cyclin B leads to inactivation of CDK1 kinase, whereas degradation of Securin activates Separase, the enzyme required for the cleavage of cohesin molecules that hold sister chromatids together (reviewed in Nasmyth and Haering, 2009).

To prevent the premature separation of sister chromatids, the checkpoint protein Mad2 is recruited to kinetochores and is released either alone or in complex with other proteins that interact with and inhibit the APC/C activator Cdc20. This mechanism ensures that a single unattached kinetochore is sufficient to inhibit APC/C activity, preventing anaphase onset until all kinetochores become attached (Rieder *et al.*, 1995). In addition to Mad2, BubR1 and Bub3 can also directly bind to the APC/C-Cdc20 and inhibit its ubiquitin ligase activity (reviewed in Musacchio, 2011). Once all kinetochores become stably attached the SAC is satisfied, Cyclin B and Securin become degraded and the cohesion between sister chromatids is resolved, allowing spindle forces to pull them apart (Figure 2(a)). These movements are initially generated by shortening of the kinetochore microtubules during anaphase A, which is driven by increased microtubule depolymerization at the kinetochore (known as the Pacman mechanism), as well as through microtubule depolymerization near the poles, both of which contribute to chromosome segregation in different species and cell types (Maiato and Lince-Faria, 2010; Figure 2(b)). This is normally followed by motor protein-driven microtubule sliding and spindle elongation, further contributing to chromosome segregation during anaphase B (Figure 2(c)).

Spindle Disassembly and Cytokinesis

Due to the decline in CDK1 activity, the mitotic spindle disassembles as chromosomes start to decondense and the nuclear envelope reforms around the two daughter nuclei. Nuclear envelope reformation and chromosome decondensation are additionally negatively regulated by a gradient of Aurora B activity spreading from the spindle midzone (Afonso *et al.*, 2014; Fuller *et al.*, 2008). The spindle midzone is also required for the assembly of the centralspindlin complex, which governs the positioning and activation of the cortical actin-myosin contractile ring that is assembled at the inner side of the plasma membrane to initiate cytokinesis (reviewed in Green *et al.*, 2012). As the actin-myosin ring contracts, a cleavage furrow forms, which pulls the cell membrane inward and surrounds the central spindle to

become compacted into the so-called midbody (Figure 2(d)). The midbody is then finally dismantled (Guizetti *et al.*, 2011), cell division is terminated, and two daughter cells are completely separated.

Glossary

Cartwheel An early scaffolding structure assembled during centriole replication, consisting of a central hub with nine radial spokes that establishes the ninefold symmetry of the centriole.

Centriole A microtubule-based, barrel-like structure, approximately 200 nm in diameter and 450 nm long, forming the core of the centrosome.

Centrosome An organelle containing two similar but not identical centrioles embedded in a pericentriolar material.

Daughter centriole The younger centriole of the centriole pair.

Distal appendages and sub-distal appendages Stick-like structures that are attached to the distal end of the mother centriole.

Mother centriole An appendage-bearing centriole that is older than the daughter centriole.

Pericentriolar material A layered network of proteins surrounding the proximal ends of the centrioles.

Primary cilium A sensory organelle at the surface of the cell that is formed from the distal end of the mother centriole.

Procentriole A newly forming centriole assembled around a cartwheel.

Introduction

The centrosome is present in many organisms, including yeast where it is referred to as a spindle pole body, but is absent from plants. Two scientists, Van de Beneden and Boveri, almost simultaneously made the first observations of the centrosome in the late nineteenth century, although it was Boveri who gave the organelle the name 'centrosome' (central body). From their observations of the fertilized eggs of the transparent parasitic roundworm *Ascaris megalocephala*, they described the centrosome as an organelle with an attraction sphere and a central corpuscle that appeared to replicate itself and to be essential for the accurate segregation of chromosomes (Scheer, 2014). Boveri went on to show that manipulation of sea urchin embryos to produce blastomeres with too many centrosomes resulted in the formation of multipolar spindles and aberrant chromosome segregation. It is remarkable that these early observations of the centrosome are fundamentally true today and their proposed hypotheses are still the subject of investigation.

Structure of the Centrosome

At the centre of the centrosome there are two centrioles (Figure 1). These are barrel-like structures formed of microtubules that typically have a diameter of 200 nm and a length of 400–500 nm (although interspecies variation exists). In general, a centriole consists of nine sets of microtubules (microtubule blades; MB) that are arranged in a radially symmetrical manner to form the barrel of the centriole and these are tilted with respect to the barrel, giving the aspect of a ratchet wheel to transverse sections (Paintrand *et al.*, 1992). The centriole is a chiral structure as it is formed of microtubules with a defined polarity: the microtubule minus ends are at the proximal end of the centriole and the plus ends at the distal end of the centriole. The exact number of microtubules in each blade

can vary, with centrioles from *Caenorhabditis elegans* being very short and formed of singlet microtubules, those of *Drosophila melanogaster* being of intermediate size and formed of doublet microtubules, and in the case of *Homo sapiens* the proximal ends of centrioles are formed of triplet microtubules, while the distal ends are formed of doublet microtubules (Paintrand *et al.*, 1992). A triplet microtubule blade consists of a single complete microtubule, the A microtubule, of 13 protofilaments and two incomplete microtubules, the B and C microtubules, which contain 10 protofilaments each (Figure 1; Guichard *et al.*, 2013). Short links connect the A and C microtubules from neighboring MBs and help to stabilize the structure of the centriole. Tubulin posttranslational modifications, such as polyglutamylation and acetylation, also play a role in stabilizing the centriole structure and render it apparently insensitive to the action of microtubule destabilizing agents (Bobinnec *et al.*, 1998).

While the two centrioles in the centrosome share the same ninefold radial structure, they are not identical and differ both in age and composition. One of the two centrioles, the mother centriole, possesses two sets of appendages that extend from the distal end of the centriole (Paintrand *et al.*, 1992), while the other centriole, the daughter centriole, is shorter by 20% and lacks these appendages (Figure 1). Because the appendages are unique to the mother centriole, the composition of the two centrioles differs, although some proteins localizing to the sub-distal appendages, such as ninein (Delgehyr *et al.*, 2005) and Cep170 (Guarguaglini *et al.*, 2005) are also found at the proximal ends of both the mother and daughter centrioles. The daughter centriole acquires appendages after it transits through mitosis and enters the next cell cycle, when it will become a mother centriole.

Surrounding the proximal ends of each centriole is a network of proteins referred to as the pericentriolar material (PCM). The PCM used to be described as being amorphous, because of its appearance in electron micrographs, but recent high resolution microscopy studies have revealed that the

Figure 1 Structure of the centrosome. A diagram of a G1 centrosome consisting of a mother centriole (MC) and a daughter centriole (DC) attached to each other via an inter-centriolar linker. The MC possesses sub-distal appendages, which are involved in microtubule (MT) anchoring, and distal appendages, both of which the DC lacks. The right panel shows cross sections through the MC from the distal (section 1) to the proximal end (section 5) of the centriole. Note that the microtubule blades (MBs) consist of triplet MTs at the proximal end of the centriole, with one complete MT (A-MT) containing 13 protofilaments and two MTs (B- and C-MTs) that are formed of only 10 protofilaments each. At the distal end of the centrioles the MBs are formed of doublet MT (A- and B-MTs) and there is a progressive reduction in the tilt of the MBs from 45° at the proximal end to 20° at the distal end of the centriole. Adapted from Paintrand, M., Moudjou, M., Delacroix, H., Bornens, M., 1992. Centrosome organization and centriole architecture: Their sensitivity to divalent cations. *Journal of Structural Biology* 108, 107–128. The MBs are interconnected by A-C linkers and spurs also protrude from the C-MT into the centriolar lumen. Surrounding the proximal ends of the centrioles is the pericentriolar material (PCM), from which MTs are nucleated and in which procentrioles are assembled during centriole duplication. While the exact structure of the PCM has not been fully elucidated, recent work has shown that its components are organized into concentric layers surrounding the centrioles. A few PCM components are represented in the diagram, some of which, such as CDK5RAP2 and pericentrin, traverse the concentric layers and are oriented with their C-termini closest to the centriolar barrel and their N-termini facing outward.

PCM is highly ordered, consisting of concentric defined layers of proteins. Some of the proteins within these layers, such as pericentrin and CDK5RAP2, are oriented in a specific direction with their C-termini being located closer to the centriolar

barrel than their N-termini (Mennella *et al.*, 2014). The PCM is crucial for the function of the centrosome as it is the site from which microtubules are nucleated and is also the site where new centrioles, procentrioles, are assembled during replication

of the centrosome. PCM size is regulated throughout the cell cycle and there is a dramatic recruitment of PCM proteins to the centrosome during mitosis in a process that is referred to as centrosome maturation.

The mother and daughter centrioles are connected to one another by fibers emanating from their proximal ends, which are at the same time both flexible, to enable inter-centriolar movement (Piel *et al.*, 2000), and robust enough to maintain cohesion between the two centrioles. Cohesion between the mother and daughter centriole is maintained throughout most of the cell cycle, but it is disrupted in late G2, through the concerted action of kinases (Agircan *et al.*, 2014) to allow the mother and daughter centrioles, which will have replicated at this point (see next section), to separate and participate in bipolar spindle formation.

Centriole Duplication

The centrosome is subject to strict copy number control and is duplicated only once per cell cycle. In G1 phase a cell usually possesses a single centrosome, containing a mother and a daughter centriole, but during the course of interphase the centrioles duplicate so that by the time a cell reaches G2 phase it has two centrosomes. Only one new centriole, a procentriole, is assembled at each existing centriole, meaning that at the end of G2 phase there are three generations of centrioles present in the cell, with one centrosome containing the mother centriole and a procentriole and the other containing the daughter centriole and a procentriole. How centriole duplication is controlled to ensure that only one procentriole forms at each existing centriole is not fully understood, but there is a licensing mechanism governing this process. It seems that once a procentriole begins to be assembled and is attached or engaged orthogonally to an existing centriole, another procentriole cannot form (Tsou and Stearns, 2006). Only when the procentrioles have disengaged from their parental centrioles, a process that takes place during mitosis, can centriole duplication occur again. In the absence of this licensing mechanism centriole amplification could occur and ultimately lead to chromosome instability (CIN) due to the improper segregation of chromosomes (Ganem *et al.*, 2009).

Many of the structural and regulatory components involved in centriole duplication were identified from RNAi and mutagenic screens carried out in *Drosophila* and *C. elegans* (Table 1; Dammermann *et al.*, 2004; Delattre *et al.*, 2004; Dobbelaere *et al.*, 2008; Leidel *et al.*, 2005). Procentriole assembly begins at the G1/S phase transition with the formation of a cartwheel structure that is attached to the proximal end of each existing centriole via a stalk (Guichard *et al.*, 2010). A cartwheel consists of a central hub with nine spoke arms (Figure 2). One of its key components is spindle assembly abnormal protein 6 (SAS-6) (Dammermann *et al.*, 2004; Leidel *et al.*, 2005), which is capable of oligomerizing via domains within its N-terminus, to form a ring-shaped structure with stalks emanating from it (Kitagawa *et al.*, 2011; van Breugel *et al.*, 2011). The radial periodicity of these stalks is 40° and corresponds well to the organization of the spoke arms, suggesting that SAS-6 alone might be responsible for conferring the ninefold symmetry to the centriole. It is to the spoke arms that the microtubule blades are attached, beginning with the A microtubule, which is capped at its minus end and elongates in a unidirectional manner (Guichard *et al.*, 2010). In contrast, the B and C microtubules are not capped and are extended from both their plus and minus ends (Figure 2). Capping of the plus ends of centriolar microtubules is important for regulating the overall length of the procentriole/centriole and CP110 has been identified as one of the factors controlling this process (Kleylein-Sohn *et al.*, 2007; Kohlmaier *et al.*, 2009; Schmidt *et al.*, 2009). Procentriole assembly also requires SAS-5/Ana2/SCL/TAL1 interrupting locus (STIL; Arquint *et al.*, 2012; Delattre *et al.*, 2004; Stevens *et al.*, 2010; Tang *et al.*, 2011; Vulprecht *et al.*, 2012), and Cep135 (Kleylein-Sohn *et al.*, 2007), which are probably cartwheel components, as well as Cep120 (Comartin *et al.*, 2013; Lin *et al.*, 2013) and SAS-4/CPAP (Kirkham *et al.*, 2003; Kohlmaier *et al.*, 2009; Leidel and Gonczy, 2003; Schmidt *et al.*, 2009; Tang *et al.*, 2009), which participate in the elongation of centriolar microtubules. Procentriole elongation is only finalized in mitosis and is dependent upon the recruitment of proteins such as hPOC5 (proteome of centriole 5) to the distal ends of procentrioles (Azimzadeh *et al.*, 2009).

There are many factors controlling the regulation of centriole duplication but there is one master regulator the kinase

Table 1 Key proteins required for centriole duplication

Caenorhabditis elegans	Drosophila melanogaster	Homo sapiens	Function
SAS-4	DSAS-4	CPAP	Involved in the assembly of the microtubule blades on to the cartwheel, as well as controlling centriole length
SAS-5	Ana2	STIL	Interacts with CPAP, probably a component of the cartwheel structure
SAS-6	DSAS-6	Hs SAS-6	Major cartwheel component dictating the ninefold symmetry of the procentriole/centriole
–	–	Cep120	Interacts with CPAP and regulates centriole length
–	Cep135	Cep135	Interacts with SAS-6 and CPAP suggesting that it is part of the pinhead
–	Asterless	Cep152	Scaffolding protein interacting with CPAP and PLK4
SPD-2	DSPD-2	Cep192	Controls PCM size and tethers PLK4 to centrioles
–	CP110	CP110	Caps centrioles and is involved in regulating centriole length
γ-Tubulin	γ-Tubulin	γ-Tubulin	Caps the minus end of the A-microtubule and localizes to a site within the lumen of the centriole
ZYG-1	SAK	PLK4	Master regulatory kinase controlling centriole assembly

Polo-like kinase 4 (PLK4) (Habedanck *et al.*, 2005), which is also known as Snk/Plk-akin kinase (SAK) in *Drosophila* (Bettencourt-Dias *et al.*, 2005) and its functional equivalent in *C. elegans* is ZYG-1 (O'Connell *et al.*, 2001). Overexpression of PLK4 can bypass the centriole licensing mechanisms and trigger centriole amplification, with multiple procentrioles forming around each parental centriole instead of just one. Due to its prominent role in centriole duplication, much attention has been focused on the regulation of PLK4 levels in the cell. PLK4 auto-regulates itself by trans-autophosphorylating residues within a degron motif located just outside its kinase domain, which targets the kinase for destruction via SCF ^{β -TrCP}-mediated ubiquitinylation (Cunha-Ferreira *et al.*, 2009; Guderian *et al.*, 2010; Rogers *et al.*, 2009; Sillibourne *et al.*, 2010). Counterbalancing this auto-destructive activity is the phosphatase PP2A that dephosphorylates the degron motif in PLK4 and relieves the kinase from ubiquitin-mediated degradation. The anchoring of PLK4 to centrioles has also been intensively studied and two PLK4-interacting proteins, Cep152 (Asterless in *Drosophila*) (Cizmecioglu *et al.*, 2010; Dzhindzhev *et al.*, 2010; Hatch *et al.*, 2010) and Cep192 (SPD-2 in *C. elegans*) (Kim *et al.*, 2013; Sonnen *et al.*, 2013) appear to act together in this process. Cep192 is involved in the recruitment of PCM to the centrosome (O'Connell *et al.*, 2000) and it is clear that there is interdependency between centriolar/centrosomal proteins for their localization to the centrosome, with the depletion of one protein affecting the centrosomal levels of another. It is important to mention that procentrioles are assembled within the PCM and in cases where the centriole duplication licensing mechanism is overridden, PCM size can influence the number of procentrioles formed. Artificial inflation of the PCM through overexpression of pericentrin in cells where procentrioles have been eliminated by laser ablation results in centriole amplification with the number formed being proportional to the amount of PCM (Loncarek *et al.*, 2008).

During centriole duplication there is the parallel process of centriole maturation, whereby the daughter centriole becomes a mother centriole. It has been observed that distal appendage proteins are recruited to the daughter centriole in late G2 (Graser *et al.*, 2007; Sillibourne *et al.*, 2013), but full maturation requires the transition through mitosis and it is in the subsequent cell cycle that the new mother centriole will fully mature by acquiring both sub-distal and distal appendages. This process is dependent on the mother centriole specific protein cenexin/ODF2 that is essential for the assembly of both the distal and sub-distal appendages (Ishikawa *et al.*,

2005). Other proteins are intimately associated to the duplication process, present in most and highly divergent species, but a comprehensive description of their roles is not yet known except in yeasts, which possess a simpler centrosome. This is the case for the centrin protein, a common marker of centrioles in most animal species, which is essential for the centrosome duplication in yeasts (Paoletti *et al.*, 2003).

Functions of the Centrosome

Microtubule Nucleation and Anchoring

The centrosome nucleates and anchors microtubules to organize a radial microtubule array during interphase and to assist in bipolar spindle formation during mitosis (Figures 3(a) and (b)). Microtubule nucleation is promoted by a number of factors but the most important is the γ -tubulin ring complex (γ -TuRC), which comprises six different subunits, γ -tubulin, GCP2, GCP3, GCP4, GCP5, and GCP6 (Teixido-Travesa *et al.*, 2012). In addition to these γ -TuRC components there are also a number of accessory factors including GCP-WD/Nedd1 and Mozart. Up to 80% of γ -tubulin is cytoplasmic (Moudjou *et al.*, 1996) and its centrosomal level varies during the course of the cell cycle, with it being at its lowest in early G1 and highest in M phase (Khodjakov and Rieder, 1999; Piehl *et al.*, 2004). The mitotic recruitment of microtubule nucleating factors to the centrosome is referred as centrosome maturation and is governed by the kinases Aurora A and PLK1 (Haren *et al.*, 2009). These phosphorylate the γ -TuRC accessory factors GCP-WD/Nedd1 and promote the recruitment of the γ -TuRC to the centrosome, leading to increased microtubule nucleation.

In addition to nucleating microtubules, the centrosome also anchors microtubules via the sub-distal appendages located on the mother centriole. This not only helps to generate a radial microtubule array, it also enables the mother centriole to position itself at the center of the cell (Piel *et al.*, 2000). Upon entry into mitosis, the sub-distal appendages are disassembled, resulting in decreased microtubule anchoring, coincident with increased nucleation activity.

Centrosomes in Cell Division

While there is a dramatic increase in the microtubule nucleation capacity of centrosomes during mitosis, they are not essential for bipolar spindle formation (Figure 3(b)), as this

Figure 2 Centriole duplication. Centriole duplication begins at the G1/S boundary with the assembly of a cartwheel at the proximal end of each existing centriole via a stalk (light green line). The cartwheel serves as a template for the assembly of a new centriole (procentriole) and consists of a hub from which nine spoke arms emanate. At the ends of the spoke arms there are pinhead structures to which the A-microtubules are connected and are elongated in a unidirectional manner. The B- and C-microtubules are elongated bidirectionally along the A-microtubules to form the centriolar barrel. Some distal luminal proteins, such as centrin and CP110, are recruited to the procentrioles after initiation of assembly (represented as grey rectangles). Procentriole elongation continues throughout interphase and is only completed in mitosis. Several structural changes occur at the mother centriole during late G2, notably the remodelling or disassembly of the sub-distal appendages to form a halo surrounding the mother centriole. In some cell lines, such as HeLa cells, the distal appendages are also disassembled although other cell lines maintain their distal appendages throughout the cell cycle. The inter-centriolar linker is dissolved at this point in the cell cycle, allowing the replicating centrosomes to separate (indicated by arrows). In mitosis (M) the cartwheel structures are disassembled from the procentrioles, which disengage from their parental centrioles. Upon exit from mitosis the sub-distal and distal appendages are assembled on the old and the new mother centriole (NMC). For simplicity the PCM is not shown in the figure although it should be noted that procentrioles do not possess their own PCM and only acquire it when they have matured to daughter centrioles.

Microtubule organization

Bipolar spindle formation

Establishing polarity

Primary cilium formation

can occur through a chromatin-mediated pathway. However, centrosomes expedite bipolar spindle formation and in their absence the rate of CIN increases, indicating that they are required for maintaining genomic integrity (Sir *et al.*, 2013). Centrosomes also participate in the final stages of division, cytokinesis and abscission, where one of the two mother centrioles usually moves toward the cytokinetic bridge connecting the two daughter cells and apparently triggers cell abscission (Piel *et al.*, 2001).

Establishing Polarity

The idea that the centrosome is able to establish cell polarity was suggested by van Beneden in 1883, when he realised that a line drawn through the centrosome and the center of the nucleus defined an axis of polarity (Figure 3(c); Harris, 2000). In migrating adherent cells, such as fibroblasts, the centrosome is often positioned in front of the nucleus although this is not always the case, with the centrosome being located behind the nucleus in migrating non-adherent or weakly adherent cells, such as neutrophils. Regardless of the position of the centrosome relative to the nucleus, polarization of the microtubule network is still observed in both cases. The example shown in Figure 3(c) represents a cell confined on a crossbow-shaped adhesive micropattern, mimicking a migrating adherent cell, which has an asymmetrical microtubule (MT) array with more MTs orientated toward the leading edge than the trailing edge due to MT plus end stabilization at the leading edge (Théry *et al.*, 2006). This plus end MT stabilization reinforces cell polarity established by the centrosome. The close association between the centrosome and the Golgi apparatus (GA) establishes polarity by directing asymmetrical intracellular trafficking. One protein that is particularly important in mediating the connection between the centrosome and the GA is AKAP450 (A kinase-anchoring protein 450). This connection is important for coordinating directed trafficking, as the disruption of AKAP450 function through the overexpression of fragments responsible for targeting AKAP450 to the GA perturbs cell migration and the trafficking of vesicles from the GA (Hurtado *et al.*, 2011). These findings highlight the important role the centrosome plays in directing intracellular trafficking and establishing cell polarity.

Primary Cilium Formation

One of the key functions of the mother centriole, likely due to the evolutionary origin of the centrosome, is to template the assembly of a primary cilium, a sensory organelle that forms at

cell surface (Figure 3(d)). This is a multistep process that involves the recruitment of membrane to the distal end of the mother centriole, where it forms a vesicle capping the end of the centriole and into which the centriolar doublet microtubules are elongated to create an axoneme. During the process of primary ciliogenesis the mother centriole is anchored to the cell cortex, to enable extension of the primary cilium into the extracellular environment, and it is often referred to as a basal body in this context. Formation of a primary cilium is crucial for embryonic development and mutations in centrosomal proteins result in diseases known as ciliopathies that are characterized by mental retardation, polydactyl and retinal degeneration. Phylogeny of centrosome-associated proteins supports the notion that the centrosome evolved by direct filiation from the ancestral and highly conserved basal body/axoneme, i.e., of a cell compartment participating in two functions essential for cell polarity, sensation, and motion. Its reproduction based on a conservative mechanism (old/new) allows the transmission of polarity to daughter cells during cell division. Asymmetric orientation of activities in animal cells is critical for development and morphogenesis, for locomotion and chemotaxis, of multicellular organisms, and impaired cell polarity is the hallmark of malignant transformation. Only metazoa have evolved a centriole/basal body-containing centrosome and conserved all functions critical for cell polarity associated with the ancestral basal body/axoneme, sensation, motion and division. At the uni- to multicellular transition that lead to metazoa, selective pressure to maintain individual cell polarity could have triggered the transition from the plasma membrane-associated basal body/flagellum to the cytoplasmic centrosome, when growth requirements are no longer needed, to switch back to the former type of cell polarity by growing a primary cilium (Bornens, 2012). The transition from centrosome-to-primary cilium – a sensory organelle in quiescent cells – corresponds to a switch in cell polarity architecture.

The Centrosome in Development

There has been much debate as to whether the centrosome is necessary for development. The planarian *Schmidtea mediterranea* possesses ciliated epithelia and thus basal bodies/centrioles but lacks centrosomes, having lost centrosomal genes during evolution, and develops fully in the absence of centrosomes (Azimzadeh *et al.*, 2012). On the other hand, studies in *Drosophila* have shown that centrosomes are required for early embryonic development, but are dispensable for later stages of development. Loss-of-function mutations in 'asterless' (Cep152), probably the only PLK4-anchoring protein in

Figure 3 Functions of the centrosome. (a) The centrosome acts as a microtubule-organizing center by nucleating microtubules from the PCM and through the anchoring microtubules to the sub-distal appendages of the mother centriole. (b) At the end of G2 phase, the amount of PCM associated with the centrioles begins to increase, as does the microtubule nucleation capacity of the centrosome, thereby aiding in the formation of a bipolar spindle and ensuring the accurate segregation of sister chromatids. (c) The centrosome establishes polarity in the cell by organizing microtubules and through its connection with the Golgi apparatus that directly influences intracellular trafficking (image adapted from Théry, M., Racine, V., Piel, M., *et al.*, 2006. Anisotropy of cell adhesive microenvironment governs cell internal organization and orientation of polarity. Proceedings of the National Academy of Sciences 103, 19771–19776). (d) Upon exit from the cell cycle and entry into a quiescent state (G0), most cells form a primary cilium, a sensory organelle located at the surface of the cell. This is formed from the distal end of the mother centriole through the extension of the A- and B-microtubules to create an axoneme that is covered by a membrane sheath. At the base of the primary cilium, where the distal appendages are located, the ciliary membrane is invaginated to form a structure referred to as the ciliary pocket. In the left panel, showing cells, the DNA is labelled in blue, microtubules in green, the Golgi apparatus in yellow and centrosomes in red.

Drosophila, cause arrest in embryonic development soon after fertilization, whereas DSAS-4 mutants are able to develop into adult flies. However, these DSAS-4 mutant flies, while appearing morphologically normal, lack cilia in their sensory neurons and consequently exhibit an uncoordinated phenotype, being unable to walk or fly, and die soon after hatching. Male DSAS-4 flies are also sterile because their sperm lack flagella (Basto *et al.*, 2006; Varmark *et al.*, 2007). In the case of *C. elegans*, centrosomes are essential for embryonic development, where the first division is asymmetric and produces two founder cells of different fates. This is achieved by the segregation of different polarity factors, PAR proteins, to the anterior and posterior sides of the zygote and acentric positioning of the bipolar spindle that forms during the first division. Depletion of either SPD-2/Cep192 (O'Connell *et al.*, 2000) or SPD-5 (Hamill *et al.*, 2002), results in defective segregation of the PAR proteins and failed asymmetric division due to impaired PCM recruitment and microtubule nucleation, demonstrating the importance of the centrosome in this process.

Asymmetric cell division is also important for maintaining stem cell populations, so that one cell retains its self-renewing potential, while the other differentiates to a specialized cell type. In *Drosophila*, the male germline stem cells (GSCs) are maintained within a niche, where they are attached to hub cells and undergo asymmetric cell division to produce one cell that differentiates and another that maintains its stem cell fate. During this asymmetric division the older mother centriole is inherited by the stem cell, closest to the hub, while the differentiating cell receives the daughter centriole (Figure 4(a)). The asymmetric partitioning of the mother centriole is thought to be linked to its greater microtubule nucleating capacity that enables it to anchor to the hub/GSC interface (Yamashita *et al.*, 2007). It has been shown that if the mother centrosome is not positioned at the hub/GSC interface, cell cycle arrest occurs until it is repositioned (Cheng *et al.*, 2008). This delay serves as a mechanism to preserve the stem cell population, but it causes a reduction in both the size of the differentiating cell population and the rate of spermatogenesis. In ageing male *Drosophila*, centrosome misorientation occurs more frequently and this correlates with reduced spermatogenesis, demonstrating that asymmetric centrosome segregation is important for maintaining stem and differentiating cell populations. While the mother centriole is inherited in GSCs, a different scenario takes place in neuroblasts of the same species where the daughter centriole is inherited by the stem cell (Conduit and Raff, 2010; Januschke *et al.*, 2013). The relevance of this difference still remains to be determined.

Differences in mother versus daughter centriole inheritance have also been observed during asymmetric cell division in the mouse developing neocortex. Radial glial progenitors divide asymmetrically at the ventricular zone (VZ) to produce a self-renewing glial cell and a differentiating cell, usually a neuron, which migrates away from the VZ to form the cortical plate of the neocortex (Figure 4(b)). In this asymmetric cell division the self-renewing glial cell invariably inherits the older (mother) centrosome and this is important for maintaining the progenitor pool, as the ablation of ninein by RNAi results in depletion of cells from the VZ (Wang *et al.*, 2009). Asymmetric centrosome inheritance might have importance

Figure 4 Asymmetric centrosome inheritance. (a) In *Drosophila*, male germline stem cells (GSCs) divide asymmetrical to produce a self-renewing stem cell and a differentiating cell (DC). The mother centrosome of the GSC nucleates more microtubules and is anchored to the side closest to the hub; during division the GSC invariably inherits the mother centrosome while the differentiating cell inherits the daughter centrosome. It should be noted that this situation is reversed in *Drosophila* neuroblasts where the stem cell inherits the daughter centrosome rather than the mother centrosome. (b) In the developing mouse neocortex, the mother centrosome is inherited by the radial glial progenitor cell (RGP), after dividing close to the ventricular zone, while the daughter centrosome is inherited by the differentiating cell (DC), which will ultimately become a neuron.

consequences for the fate of the cell, as it has been shown that the older mother centriole forms a primary cilium before the newly formed mother centriole and has the ability to respond to extracellular signals first (Paridaen *et al.*, 2013).

Finally, somatic centrosomes are able to induce parthenogenesis – development in the absence of fertilization – in amphibian eggs. The pricking of *Xenopus* oocytes has been found to trigger cell cycling resumption but it does not result in cell cleavage or development, whereas the injection of centrosomes, even when they are heterologous, induces parthenogenesis (Tournier *et al.*, 1989). Furthermore, only replication competent somatic centrosomes are capable of inducing parthenogenesis, indicating that duplication of the centrosome is required for development.

Centrosome in Disease

The centrosome has long been implicated in cancer. Examination of tumor biopsies revealed that cancerous cells

frequently possessed supernumerary centrosomes capable of nucleating microtubules, leading to the suggestion that these additional microtubule-organizing centers (MTOCs) could lead to multipolar spindle formation, unequal chromosome segregation, and aneuploidy (**Figure 5(a)**), an idea first proposed by Boveri in 1902 (**Boveri, 2008**). Testing of this hypothesis has proven difficult, because centrosome amplification can occur as a result of cell division defects, and has it required the use of model systems such as *D. melanogaster*, in which centrosome amplification can be induced in a controllable manner to address this problem. Induced overexpression of SAK/PLK4 in developing fly embryos after the early syncytial stage, during which centrosomes are essential (**Varmark et al., 2007**), results in a short developmental delay due to the presence of supernumerary centrioles, but the flies develop normally and exhibit only a low level of aneuploidy (**Basto et al., 2008**). This is due to an efficient centrosome clustering mechanism that is dependent on the non-essential kinesin *ncd*/HSET and enables a bipolar spindle to form that contains multiple centrosomes at each pole (**Basto et al., 2008; Kwon et al., 2008**). However, subsequent transplantation of larval brain cells, containing supernumerary centrosomes, into wild-type hosts resulted in metastatic tumor formation, demonstrating that centrosome amplification can promote tumorigenesis (**Basto et al., 2008**). Centrosome loss or centrosome dysregulation can also lead to tumor formation in

Drosophila larval neural stem cells, reiterating the importance of the centrosome in maintaining cell polarity during asymmetric stem cell division (**Castellanos et al., 2008**).

Inhibitors of HSET are being developed (**Watts et al., 2013**) because inhibition of its activity does not affect division in normal cells, but it disrupts centrosome clustering in cancer cells, causing them to form multipolar spindles and produce unviable progeny that undergo apoptosis (**Ganem et al., 2009**). Even though centrosome clustering mechanisms exist to prevent multipolar spindle formation, supernumerary centrosomes still contribute to CIN by promoting the formation of merotelic kinetochore-microtubule attachments (**Ganem et al., 2009**), where microtubules from the two opposing spindle poles attach to a single kinetochore (**Figure 5(b)**). This type of attachment satisfies the spindle assembly checkpoint (SAC), thereby allowing chromatid separation, and results in chromosome missegregation due to the presence of a lagging chromosome (**Ganem et al., 2009**).

Summary

- The centrosome consists of two microtubule-based centrioles (a mother and a daughter centriole) that differ in age and are structurally similar but not identical.
- The centrosome is the major microtubule-organizing center in the cell.

Figure 5 Centrosome amplification. (a) Upon entry into mitosis, cells possessing supernumerary centrosomes form bipolar spindles, unless centrosome clustering mechanisms fail, in which case multipolar spindles form. (b) Supernumerary centrosomes promote merotelic attachment where microtubules from opposing poles attach to a single kinetochore (orange microtubule), which can lead to aneuploidy due to chromosome missegregation.

- During interphase the centrosome is responsible for creating a microtubule array and during mitosis it assists in bipolar spindle assembly.
- Tissue development and homeostasis depend on the polarizing activity of the centrosome.
- The centrosome is involved in cell cycle progression and interconverts to a primary cilium when the cell enters a quiescent state (G0).
- Centrosome amplification is frequently observed in tumors where it promotes CIN.
- There are many outstanding questions in centrosome biology with the precise mechanisms of centriole duplication and the centrosome-to-primary cilium interconversion remaining to be fully elucidated, as well as the centrosome's role in development and tumorigenesis.

Glossary

Axoneme The microtubule-based skeleton of cilia and flagella, which usually consists of nine peripheral outer doublets of microtubules and 0 or 2 central microtubule singlets. In motile (9 + 2) cilia, the axoneme contains additional structures required for motility, including outer and inner dynein arms, radial spokes, nexin links, and central pair projections.

Basal body Modified centriole that provides the basis for the outgrowth of the ciliary and flagellar microtubule skeleton, the axoneme.

Centriole Tubulin-based barrel-shaped Encyclopedia of Cell Biology structure composed of 9 microtubule triplets.

Centrioles are the core components of the centrosome and also function as basal bodies in cells with cilia or flagella.

Centrosome Microtubule organizing center composed of two orthogonally arranged centrioles and pericentriolar material, which nucleates and anchors microtubules.

During mitosis, centrosomes function as mitotic spindle poles. In ciliogenesis, the older of the two centrioles (the mother centriole) functions as the basal body from which the ciliary axoneme emanates.

Ciliopathy Genetic disorder whose affected gene product (s) localizes to the cilium-centrosome axis.

Dyneins Motor proteins that consist of several subunits and move from the plus to the minus end of microtubules upon hydrolysis of ATP. In cilia and flagella, dyneins provide the force for motility and for retrograde intraflagellar transport.

Intraflagellar transport Process by which proteins are transported along the axoneme of the cilium from the base to the tip and back. Intraflagellar transport is essential for assembly and maintenance of most cilia and flagella, and is powered by kinesin and dynein motor proteins.

Kinesins Motor proteins that move along microtubules upon hydrolysis of ATP. Most kinesins move toward the plus end of microtubules, but some can move towards the minus end and promote microtubule disassembly.

Primary cilium A non-motile 9 + 0 cilium present in a single copy on the surface of many quiescent or differentiated vertebrate cells. Primary cilia are enriched for numerous signaling proteins and play important roles during development and in the adult as coordinators of many different signaling pathways.

Transition zone Region between the basal body and the cilium proper, which is thought to act as a barrier for selective transport of molecules into and out of the ciliary compartment.

Introduction

Cilia and flagella are microtubule-based organelles protruding from the surface of a wide variety of eukaryotic cells. There are two general types of cilia: motile cilia and non-motile cilia. Motile cilia are usually present in large numbers per cell, for example, in the epithelium of the human airway, oviduct and brain ventricles, or on the surface of protists such as *Paramecium* and *Tetrahymena* (Figure 1(a)). These cilia beat with a forward power stroke and a backward recovery stroke and function in cell locomotion or movement of fluid across epithelia. Flagella are also motile, but are usually present in a single copy per cell and motion is often planar and wave-like from base to the tip of the organelle producing a propellar-like motion (Figure 2(a); Ibanez-Tallon *et al.*, 2003; Satir and Christensen, 2006; Ginger *et al.*, 2008). Flagella and motile cilia are ultrastructurally similar (the terms cilia and flagella are used interchangeably), typically comprising a 9 + 2 microtubule axoneme with radial spokes (RS) and outer (ODAs) and inner (IDAs) dynein arms (Figures 1(b), and 1(c)). Non-motile cilia, such as the so-called primary cilia (Sorokin, 1968), which are present on many cell types of the human body, are solitary organelles that function as specialized signaling devices (Satir and Christensen, 2006; Satir *et al.*, 2010). These cilia typically have a 9 + 0 axoneme and lack motility-related structures such as dynein arms (Figures 1(b), and 1(c)).

Proteomics, transcriptomics, and comparative genomics studies have revealed that cilia contain hundreds of different proteins, many of which are highly conserved between different species (Arnaiz *et al.*, 2009). Some of these proteins assemble to form the elaborate structures of the microtubule axoneme or are incorporated into the ciliary membrane that surrounds it. Cilia are typically rod-shaped, ranging in length from a few (e.g., chondrocyte primary cilia) to several hundred microns in length (e.g., olfactory cilia). Some types of non-motile cilia have a highly specialized morphology. For example, the vertebrate rod and cone photoreceptors consist of an inner segment linked to the outer segment by a short connecting cilium, which ends in a highly differentiated outer segment composed of a cylinder-shaped stack of membrane disks (Insinna and Besharse, 2008). Certain neuronal sensory cilia of the nematode *Caenorhabditis elegans* also display atypical cilia with wing- or finger-like membranous appendages (Silverman and Leroux, 2009).

Although motile and non-motile cilia differ in their axoneme structure and function, all cilia have the ability to perceive signals from the environment and transmit these to the cell body (Christensen *et al.*, 2007). While it has been known for many years that motile cilia are important for many physiological processes, such as sperm locomotion and clearance of mucus from the airways (Ibanez-Tallon *et al.*, 2003), the functional importance of non-motile cilia has only recently

Figure 1 Overview of different types of cilia and flagella. (a) Examples of organisms and cell types with different types of motile or non-motile cilia. been appreciated. For example, primary cilia were discovered more than a century ago (Zimmermann, 1898) but were, until recently, considered vestigial organelles. It is now well established that primary cilia are indispensable sensory organelles that coordinate a variety of important signaling pathways during development and in tissue homeostasis (Goetz and Anderson, 2010; Satir *et al.*, 2010). Consequently, mutations in genes that lead to dysfunction of motile or primary cilia can lead to diseases and developmental defects in humans. These

diseases are called ciliopathies (Ibanez-Tallon *et al.*, 2003; Hildebrandt *et al.*, 2011).

Structure of Cilia and Flagella

Motile cilia and flagella are widely used in protists and metazoans for locomotion, extracellular fluid flow and sensory perception (Ibanez-Tallon *et al.*, 2003; Ginger *et al.*, 2008).

Figure 2 Structural and functional features of motile cilia and flagella. (a) Distinct beating patterns of motile cilia in different organisms and cell types. Cilia on multi-ciliated epithelial cells and *Chlamydomonas* use a power stroke (black lines) followed by a recovery stroke (gray lines) for movement in or of extracellular fluid. In contrast, single motile cilia on the embryonic node of vertebrates rotate around a tilted axis (dashed line) to establish a morphogen gradient and/or to induce Ca^{2+} influx in crown cells on the left-hand side of the node, via activation of the polycystins (PC2 and the PC1 homolog, PC1 like 1) in mechanosensory, immotile primary cilia, which is necessary for the establishment of left-right symmetry (Hirokawa *et al.*, 2006). The flagellum of sperm cells oscillates during locomotion. Black arrow represents net flow. (b) Cartoon illustrating cross-section of a motile 9+2 cilium showing associated structures on microtubule outer doublets (left; A and B) or central pair microtubules (right; C1 and C2), including the RS, ODA, IDA, kinases PKA and CK1, phosphatases PP2A and PP1, AKAP240 and RSP3, calmodulin complexes, and central pair appendages (gray). Figure panels redrawn from Okada *et al.* (2005), Wirschell *et al.* (2011), and Wirschell *et al.* (2013) and the website of Dr. Charles Lindemann, Oakland University (<http://www2.oakland.edu/biology/lindemann/cf.htm>) with permission.

They consist of a microtubule-based skeleton called axoneme, which extends from a specialized centriole called a basal body, and is surrounded by a bilayered ciliary membrane (Figure 1(c)). The axonemal microtubules are oriented with their growing (plus end) toward the cilium tip (Johnson and Rosenbaum, 1992) and comprise nine peripheral microtubule doublets, each containing an A-tubule fused with a B-tubule, which form a ring-shaped structure connected by nexin links. In addition to the nine peripheral microtubules, motile cilia usually contain a central pair (CP) of microtubules (9+2 configuration; Figures 1(b), 1(c), and 2(b)), although there

are exceptions to this 9+2 pattern. For example, motile cilia with 9+0 or 9+4 configuration were observed on the embryonic node of mouse and rabbit embryos (Nonaka *et al.*, 1998; Feistel and Blum, 2006) whereas non-motile cilia of the fish inner ear contain a CP (9+2 configuration) (Flock and Duvall, 1965). Thus, the presence of a CP does not always correlate with motility. Motility rather correlates with the presence of outer (ODAs) and inner (IDAs) dynein arms, which interconnect one outer axonemal microtubule doublet with the adjacent outer doublet (Figure 2(b)) and move along the doublets in a microtubule minus-end direction (Satir and

Christensen, 2006). ODAs have a homogenous structure and composition whereas IDAs are composed of at least seven different dynein isoforms (King and Kamiya, 2009). Another characteristic feature of motile cilia is the attachment of RS to the A-tubule of each microtubule outer doublet (Figure 2(b)). RS are T-shaped multiprotein complexes with a head pointing toward the CP microtubules (Yang and Smith, 2009). Appropriate attachment of the base of the RS to the A-tubule requires RS protein 3 (RSP3), an A-kinase anchoring protein (AKAP) involved in recruiting specific kinases to RS (Diener *et al.*, 1993; Wirschell *et al.*, 2008; Gaillard *et al.*, 2001, 2006).

The Basis of Motility

A common, but still incomplete, model describing the mechanical processes generating ciliary motion is based on directed movement of dynein motors from the ciliary tip to microtubule minus ends at the cilium base generating a molecular force which results in sliding of microtubule doublets along the ciliary axoneme (Sale and Satir, 1977; Fox and Sale, 1987). In this 'sliding model' sliding of microtubule doublets is temporally and spatially regulated. Controlled activation and inhibition of dynein activity across the axonemal axis and along the length leads to alternate bending of microtubule doublets in a oscillatory manner that confers cilium motility (Satir and Christensen, 2006; Lindemann and Lesich, 2010; Wirschell *et al.*, 2011). There is evidence in *Chlamydomonas* and mammalian cells that activity of ODAs regulates ciliary beat frequency whereas activity of IDAs is responsible for the waveform of the stroke (i.e., size and shape of the ciliary bend) (Brokaw, 1994; Brokaw and Kamiya, 1987; Chilvers *et al.*, 2003). Both ciliary beat frequency as well as the shape of the stroke are at least in part regulated by kinases and phosphatases that modify dynein activity and are physically attached to microtubule doublets, RS and CP usually through anchoring proteins such as AKAP240 and RSP3 (Salathe, 2007; Wirschell *et al.*, 2011). The protein network regulating dynein activity includes cAMP-dependent protein kinase (PKA), cGMP-dependent protein kinase (PKG), casein kinase 1 (CK1), protein phosphatase (PP)1 and 2A, and the dynein regulatory complex (DRC) (Figure 2(b); Wirschell *et al.*, 2009, 2011).

The processes underlying ciliary motion are very complex and still not completely understood. However, a common view is that spatial regulation of dynein activity is accomplished by direct interactions of RS heads with CP microtubules and further signal transmission via the DRC to dynein arms (Lindemann and Lesich, 2010; Wirschell *et al.*, 2011). Indeed, RS-CP interaction is regulating microtubule doublet sliding and can inhibit IDA activity (Smith and Sale, 1992; Witman *et al.*, 1978; Nakano *et al.*, 2003). The CP-associated protein Hydin is involved in the regulation of dynein activity possibly through its interaction with RS heads (Lechtreck and Witman, 2007). Notably, Hydin mutations cause Hydrocephalus in mice and humans due to motility defects in cilia in the brain causing insufficient transport of cerebrospinal fluid (Lechtreck *et al.*, 2008; Olbrich *et al.*, 2012). Moreover, regulation of dynein activity requires association of the DRC with ODAs and IDAs (Wirschell *et al.*, 2009, 2011). High-resolution cryoelectron tomography revealed that nexin is part of the

DRC, referred to as nexin-DRC, which interconnects outer microtubule doublets with ODAs and IDAs acting as a regulatory hub to control activity of dynein motors (Nicastro *et al.*, 2006; Heuser *et al.*, 2009). Indeed, nexin-DRC associates with inner dynein I1 and activity of I1 subunit IC138 is critical for dynein activity and microtubule sliding (Bower *et al.*, 2009; Heuser *et al.*, 2012). Importantly, mutations in the gene encoding the nexin-DRC subunit DRC1 cause primary ciliary dyskinesia (PCD) in humans (Wirschell *et al.*, 2013).

Ciliary Tip Structures

The distal tip of motile cilia typically features a central cap and filaments that link the microtubule ends to the ciliary membrane (Figure 1(c)). The organization and structure of these tip complexes vary among species and cell types, and their composition is not well understood (Fisch and Dupuis-Williams, 2011). Some of the proteins known to localize specifically to the ciliary tip include the EF-hand Ca^{2+} binding domain-containing protein Sentan (Kubo *et al.*, 2008), microtubule plus end-tracking EB proteins (Pedersen *et al.*, 2003; Schröder *et al.*, 2011), and centrosomal protein (CEP) 104 (Satish Tammana *et al.*, 2013). Both EB proteins and CEP104 are required for ciliogenesis (Satish Tammana *et al.*, 2013; Schröder *et al.*, 2011; Jiang *et al.*, 2012), and lack of CEP104 causes defects in the flagellar tip structures in *Chlamydomonas* (Satish Tammana *et al.*, 2013).

Axoneme Structure of Non-Motile Cilia

Like motile cilia the axonemes of non-motile cilia typically consist of nine peripheral microtubule pairs arranged in a ring (Figure 1), but lack the structures associated with motility, for example, dynein arms and radial spokes. In addition, the central pair of microtubules is usually lacking (i.e., 9+0 configuration) although there are exceptions to this rule (Gluenz *et al.*, 2010). The axoneme tip seems to lack distinct capping structures, ending in an electron-dense area close to the ciliary membrane (Fisch and Dupuis-Williams, 2011). Nevertheless, similar to motile cilia, non-motile cilia contain specific tip proteins such as EB proteins and CEP104 (Hao *et al.*, 2011; Larsen *et al.*, 2012; Satish Tammana *et al.*, 2013).

The Ciliary Membrane

The ciliary membrane is a bilayer lipid membrane that is continuous with but chemically distinct from the plasma membrane, and contains specific lipids and membrane proteins (Nachury *et al.*, 2010; Rohatgi and Snell, 2010). It is derived from vesicles that are transported from the Golgi or recycling endosomes toward the basal body, where vesicles fuse and become incorporated into the growing ciliary membrane (Sorokin, 1962, 1968; Bouck, 1971; Papermaster *et al.*, 1985; Hsiao *et al.*, 2012; Nachury *et al.*, 2010; Sung and Leroux, 2013). Lateral transport of proteins from the plasma membrane to the ciliary membrane has also been reported (Hunnicuttt *et al.*, 1990; Milenkovic *et al.*, 2009). Structural and functional barriers at the transition zone (TZ) are thought to prevent diffusion and mixing of ciliary and plasma membrane

proteins and lipids, ensuring maintenance of a unique ciliary membrane composition (see Section 'Passage of Proteins through the Transition Zone'). The ciliary membrane is dynamic, and incorporation of lipids and membrane proteins into the ciliary membrane is counterbalanced by endocytosis at the ciliary pocket (Rattner *et al.*, 2010; Kaplan *et al.*, 2012; Benmerah, 2013) and budding of ectosomes directly from the ciliary membrane (Wood *et al.*, 2013; Wang *et al.*, 2014).

The ciliary membrane is enriched in sterols (Montesano, 1979; Iomini *et al.*, 2006; Lehtreck *et al.*, 2013) and its lipid composition is regulated by enzymes such as phospholipase D, which is actively transported into and out of cilia (Lehtreck *et al.*, 2013). Appropriate regulation of ciliary membrane lipid content is important for membrane protein localization and signaling (Rohatgi *et al.*, 2007). Many different membrane receptors and ion channels are known to be enriched in cilia (Christensen *et al.*, 2007; Nachury *et al.*, 2010; Rohatgi and Snell, 2010) and this is fundamental for the ability of cilia to regulate various signaling pathways (see Section 'Signaling Pathways Coordinated by Cilia'). Some prominent examples of ciliary membrane proteins include the polycystic kidney disease gene products polycystin-1 and -2 (Barr and Sternberg, 1999; Pazour *et al.*, 2002; Yoder *et al.*, 2002), various receptor tyrosine kinases (RTKs) (Christensen *et al.*, 2012), and the transmembrane proteins Patched 1 and Smoothened that coordinate Hedgehog (Hh) signaling (Rohatgi *et al.*, 2007).

The Transition Zone

The TZ is the region between the basal body and cilium proper, which contains structural and functional barriers that regulate the selective passage of molecules into and out of the ciliary compartment. The most obvious structural part of the TZ comprises the ciliary necklace (Figures 1(b) and 1(c)). The necklace lies above the transition fibers and, for 9 + 2 cilia, it ends at the so-called basal plate where the axonemal CP microtubules begin (Czarnecki and Shah, 2012; Szymanska and Johnson, 2012). The necklace is composed of multiple rows of the so-called 'Y-links' each consisting of a 'Champagne-glass'-like structure with a pore stem attached to the doublet microtubules and a pore cup attached to the ciliary membrane via strings of intramembrane proteins (Figures 1(b) and 1(c); Gilula and Satir, 1972). Formation of these 'Champagne-glass'-like structures requires the protein CEP290 (Craig *et al.*, 2010). Mutations in the gene encoding CEP290 or other TZ components are responsible for a large number of ciliopathies, including nephronophthisis (NPHP) and Meckel-Gruber Syndrome (MKS) (Szymanska and Johnson, 2012; Czarnecki and Shah, 2012). In some cell types, a ring-like structure formed by the oligomeric GTPase, Septin, decorates the membrane between the basal body and the transition fibers, i.e., the junction between the ciliary and periciliary membranes (Hu *et al.*, 2010; Fliegauf *et al.*, 2013). The periciliary membrane, which is often embedded in the ciliary pocket where the plasma membrane transitions into the ciliary membrane (Benmerah, 2013; Figure 1(c)), has a specialized lipid composition that is thought to be critical for regulating transport of lipids and proteins into and out of the cilium (Vieira *et al.*, 2006; Cevik *et al.*, 2013).

Ciliogenesis

All types of eukaryotic cilia and flagella are assembled onto a basal body. In general, many aspects of ciliogenesis are highly conserved among different organisms and cell types, but specific differences exist (Dawe *et al.*, 2007; Ginger *et al.*, 2008). Most axonemes assemble within the confines of the ciliary membrane (compartmentalized ciliogenesis), but the axonemes of, for example, *Drosophila* and *Plasmodium* gamete flagella are assembled in the cytosol (Tokuyasu, 1975; Sinden *et al.*, 2010). In mammalian cells with primary cilia the basal body is derived from the mother centriole of the centrosome (Paintrand *et al.*, 1992; Kobayashi and Dynlacht, 2011), whereas in multi-ciliated cells basal body formation depends on production of many new centrioles (Dawe *et al.*, 2007). In some cell types (e.g., multi-ciliated epithelial cells) the centrioles migrate to the cell surface and dock at the plasma membrane prior to ciliogenesis, whereas in other cell types (e.g., fibroblasts and smooth muscle cells) ciliogenesis is initiated within the cell body by attachment of a vesicle to the distal end of the mother centriole (Sorokin, 1962, 1968; Molla-Herman *et al.*, 2010; Dawe *et al.*, 2007). In such cells, the basal body often remains localized deep in the cell body even after cilium formation is complete, and the proximal part of the mature cilium lies within a membrane invagination known as the ciliary pocket or ciliary pit (Figure 1(c); Benmerah, 2013).

Docking of centrioles to the membrane or a vesicle depends on the centriole distal appendages (Anderson, 1972; Schmidt *et al.*, 2012; Tateishi *et al.*, 2013; Joo *et al.*, 2013; Sillibourne *et al.*, 2013), which correspond to the basal body transition fibers (Paintrand *et al.*, 1992; Tateishi *et al.*, 2013). Depletion or loss of centriolar distal appendage proteins such as ODF2, CEP164, CEP83 [CCDC41], CEP89 [CCDC123], SCLT1, and FBF1 impairs ciliogenesis (Ishikawa *et al.*, 2005; Graser *et al.*, 2007; Schmidt *et al.*, 2012; Tanos *et al.*, 2013; Tateishi *et al.*, 2013; Joo *et al.*, 2013; Sillibourne *et al.*, 2013). Once centrioles have docked to the plasma membrane or vesicle, the axoneme emerges from the distal end of the basal body (Sorokin, 1962, 1968). The axoneme keeps elongating from its distal end (Johnson and Rosenbaum, 1992) in an intraflagellar transport (IFT)-dependent manner and the growing axoneme is enclosed by membrane along its entire length (Figure 3). This membrane, which becomes the ciliary membrane, is formed by continuous docking and fusion of vesicles at the ciliary base (Figure 3; Sorokin, 1962, 1968; Hill and Outka, 1974; Papermaster *et al.*, 1985; Hsiao *et al.*, 2012; Nachury *et al.*, 2010). Trafficking of such vesicles to the ciliary base is complex and involves different sorting routes and numerous GTPases, adapters and coat proteins (Nachury *et al.*, 2010; Barenz *et al.*, 2011; Hsiao *et al.*, 2012; Deretic, 2013; Sung and Leroux, 2013). Some prominent examples include the GTPases Rab8 and Rab11 (Moritz *et al.*, 2001; Nachury *et al.*, 2007; Knodler *et al.*, 2010) as well as IFT20 (Follit *et al.*, 2006). Proteins destined for the ciliary compartment may not only be associated with such vesicles (Hill and Outka, 1974; Wood and Rosenbaum, 2014), but can also be transported in the form of non-membraneous granules called centriolar satellites (Kubo and Tsukita, 2003; Barenz *et al.*, 2011). Transport of ciliary proteins and membrane from the cytosol toward the basal body is thought to depend on cytoplasmic dynein 1,

Figure 3 Diagram of IFT and vesicle transport pathways involved in cilium assembly, disassembly, and signaling. See text for details.

which travels along cytoplasmic microtubules toward the basal body (Kubo and Tsukita, 2003; Kong *et al.*, 2013), as well as the presence of specific ciliary targeting sequences in the proteins destined for the cilium (Pazour and Bloodgood, 2008; Berbari *et al.*, 2008). Some ciliary proteins, such as components of the RS, may be preassembled in large complexes in the cytoplasm prior to transport to the cilium (Qin *et al.*, 2004).

Intraflagellar Transport (IFT)

Compartmentalized ciliogenesis relies on IFT for delivery of ciliary building blocks, produced in the cell body, to their site of incorporation in the cilium (Pedersen and Rosenbaum, 2008; Ishikawa and Marshall, 2011). Consequently, mutations in genes coding for IFT components lead to defects in ciliary assembly and function and cause disease (see Section ‘Diseases caused by defects in cilia’). IFT is the process by which granular particles (IFT particles or trains) move along axonemal outer doublet microtubules, beneath the ciliary membrane, from the basal body to the flagellar tip and back (Figure 3). IFT was first discovered in 1993 by enhanced digital interference contrast

microscopy of immobilized flagella of *Chlamydomonas*, where the particles were seen to move in the anterograde (base to tip) and retrograde (tip to base) directions at approximately $2 \mu\text{s}^{-1}$ and $3.5 \mu\text{s}^{-1}$, respectively (Kozminski *et al.*, 1993). Subsequent studies using fluorescently tagged IFT particle or motor subunits revealed similar bidirectional movement in cilia from other organisms, such as neuronal sensory cilia in *C. elegans* (Orozco *et al.*, 1999), primary cilia of cultured mammalian cells (Follit *et al.*, 2006; Tran *et al.*, 2008), and motile flagella of *Trypanosoma brucei* (Absalon *et al.*, 2008). IFT is thought to occur in all eukaryotic cilia and flagella that display compartmentalized ciliogenesis, but the specific motors employed may vary depending on organism and cell type (Pedersen and Rosenbaum, 2008; Silverman and Leroux, 2009; Ishikawa and Marshall, 2011).

The anterograde IFT motor: Kinesin-2

Studies using a temperature sensitive (ts) *Chlamydomonas* mutant in the *FLA10* gene (Adams *et al.*, 1982; Huang *et al.*, 1977), which encodes one of the two motor subunits of heterotrimeric kinesin-2, also known as kinesin-II (Walther *et al.*, 1994; Table 1), revealed that this motor is responsible for anterograde IFT (Kozminski *et al.*, 1995). Subsequent studies

IFT particle polypeptides and cargo

IFT particles were first isolated from *Chlamydomonas* flagella using sucrose density gradient centrifugation (Piperno and Mead, 1997; Cole *et al.*, 1998). The IFT particles consist of two sub-complexes termed IFT-A and IFT-B (Cole *et al.*, 1998), which comprise at least 6 and 16 different polypeptides, respectively (Table 1) (Ishikawa and Marshall, 2011; Taschner *et al.*, 2012; van Dam *et al.*, 2013). Mutations in IFT-B genes generally lead to very short or absent cilia, whereas mutations in IFT-A genes typically lead to bulbous cilia with excessive amount of IFT material (Pedersen and Rosenbaum, 2008; Ishikawa and Marshall, 2011). Thus, it is commonly accepted that IFT-B proteins participate in anterograde IFT whereas IFT-A proteins are involved in retrograde IFT. However, some IFT-A proteins also participate in anterograde IFT, and some IFT-B proteins are important in retrograde IFT (Pedersen *et al.*, 2005; Qin *et al.*, 2005; Tsao and Gorovsky, 2008; Mukhopadhyay *et al.*, 2010; Behal *et al.*, 2012; Liem *et al.*, 2012; Wei *et al.*, 2012; Keady *et al.*, 2012).

Many IFT polypeptides harbor protein–protein interaction motifs such as tetratricopeptide repeats (TPRs), WD40 repeats, and coiled coils (Cole, 2003). Phylogenetic analyses indicated that several IFT-A and IFT-B proteins share common ancestry with the COPI vesicle coat complex (Jekely and Arendt, 2006; van Dam *et al.*, 2013), two IFT-B proteins (IFT22 and IFT27) are similar to Rab-like GTPases (Schafer *et al.*, 2006; Qin *et al.*, 2007), while four of the IFT-B proteins (IFT54, IFT57, IFT81, and CLUAP1) contain calponin homology domains (Taschner *et al.*, 2012; Bhogaraju *et al.*, 2013a; Schou *et al.*, 2013). The overall structure of the IFT particle trains was analyzed by electron tomography (Pigino *et al.*, 2009), whereas biochemical, bioinformatics, and crystallography studies have provided information regarding the organization of IFT polypeptides within the IFT-A and IFT-B complexes (Lucker *et al.*, 2005; Taschner *et al.*, 2011; Behal *et al.*, 2012) as well as the three dimensional structure of individual IFT particle polypeptides and sub-complexes (Bhogaraju *et al.*, 2011, 2013a). These studies are beginning to shed light on the molecular mechanisms by which IFT particle polypeptides interact with specific ciliary cargo proteins to promote axoneme assembly (Bhogaraju *et al.*, 2013b). For example, a recent study showed that IFT81 and IFT74 of the IFT-B complex form a dimer that directly binds tubulin (Bhogaraju *et al.*, 2013a). In addition to tubulin, several other axonemal proteins were found to interact with IFT particle polypeptides, including RSPs and ODA subunits (Qin *et al.*, 2004; Ahmed *et al.*, 2008; Gao *et al.*, 2010). A recent study in *Chlamydomonas* using single-particle imaging showed that IFT is required for transport of DRC4, a component of the DRC (see Section “The Basis of Motility”), from the cell body toward the tip of flagella where the majority of IFT-bound DRC4 is released (Wren *et al.*, 2013).

In addition to transport of structural components of the axoneme, IFT may also mediate transport of ciliary membrane and signaling proteins. For example, IFT-A proteins interact with the Tubby-like protein 3 (TULP3), which in turn interacts with distinct G protein coupled receptors to mediate their ciliary localization in an IFT-dependent manner (Mukhopadhyay *et al.*, 2010). IFT proteins also interact with Bardet Biedl Syndrome proteins (Blacque *et al.*, 2004; Lechtreck *et al.*, 2009; Wei *et al.*, 2012; Domire *et al.*, 2010), which form a protein complex

called the BBSome that is involved in ciliary membrane protein trafficking (Nachury *et al.*, 2007; Loktev *et al.*, 2008; Lechtreck *et al.*, 2009; Wei *et al.*, 2012). Similar to many IFT-A and IFT-B protein, the BBSome is thought to have evolved from a coat-omer-like progenitor (van Dam *et al.*, 2013).

Passage of Proteins through the Transition Zone

The selective passage of molecules into and out of the ciliary compartment is thought to be regulated by structural and functional barriers at the TZ. The presence of such barriers or ‘ciliary pore complexes’ was first proposed by Rosenbaum and Witman (2002), due to the observation that IFT particle proteins accumulate around the transition fibers in *Chlamydomonas* (Deane *et al.*, 2001). Several recent studies support the presence of such barriers at the TZ (Craigie *et al.*, 2010; Hu *et al.*, 2010; Kee *et al.*, 2012; Breslow *et al.*, 2013; Lin *et al.*, 2013). The barriers include the Septin ring complex that is thought to limit mobility of ciliary membrane proteins (Hu *et al.*, 2010) as well as the structures of the ciliary necklace (Craigie *et al.*, 2010). In the case of non-membrane proteins, a diffusion barrier with a pore size of approximately 8–9 nm in diameter that allows diffusion of molecules below about 50–100 kD into the cilium was reported (Kee *et al.*, 2012). Larger molecules such as the DRC are actively transported across the TZ by IFT (Wren *et al.*, 2013) and probably depend on additional factors for ciliary entry. Such factors may include proteins orthologous to those operating in nuclear trafficking, including importin and components in the RanGTP cycle (Fan *et al.*, 2007; Dishinger *et al.*, 2010; Hurd *et al.*, 2011; Maiuri *et al.*, 2013). Further, proteins similar to structural components of nuclear pore complexes, nucleoporins (Strambio-De-Castillia *et al.*, 2010), may function at the ciliary base region to regulate the import of ciliary proteins (Kee *et al.*, 2012).

Once proteins have passed the ciliary necklace they may become allocated to specific areas of the ciliary compartment. Transmembrane proteins, such as Smoothed and Serotonin receptors lose contact to IFT trains and are positioned along the ciliary membrane predominantly by diffusion (Ye *et al.*, 2013). In other cases, protein localization may be regulated by yet another set of barriers that define discrete intraciliary compartments. Prominent examples include the ‘Inversin/NPHP2 compartment’ that runs for 1–2 μm above the necklace region in primary cilia of vertebrate cells (Shiba *et al.*, 2009) and the ‘Arl-13/ARL13b compartment’ that corresponds to the middle segment of sensilla in *C. elegans* (Cevik *et al.*, 2010, 2013). These compartments likely play a critical role in the regulation of processes associated with ciliary formation, maintenance, and sensory function. Finally, proteins may be positioned uniquely to the ciliary tip, such as Gli transcription factors, which when activated are transported out of the cilium for nuclear localization (Haycraft *et al.*, 2005; see Section ‘Signaling Pathways Coordinated by Cilia’).

Cilium Disassembly and Length Maintenance

Cilia are dynamic organelles that can assemble, disassemble, or regulate their length in response to cellular and environmental cues. Cilia can disassemble either by severing of the

axoneme at its base or by depolymerization of axonemal microtubules from the tip (Quarmany, 2009; Seeley and Nachury, 2010; Ishikawa and Marshall, 2011). For example, in *Chlamydomonas*, the microtubule doublets between the basal body and flagellar TZ are severed prior to mitosis to liberate the centrioles for mitotic spindle pole formation (Parker *et al.*, 2010). Severing of the axoneme likely involves the microtubule severing enzyme katanin (Rasi *et al.*, 2009) whereas disassembly of the microtubule axonemes from the tip likely involves depolymerizing kinesins such as kinesin-8 or kinesin-13 family members (Blaineau *et al.*, 2007; Piao *et al.*, 2009; Dawson *et al.*, 2007; Niwa *et al.*, 2012). In addition, several kinases such as never in mitosis gene A (NIMA)-related kinases (NEKs), mitogen activated protein kinases (MAPKs), and Aurora A-like kinases were shown to regulate cilium length and disassembly (Berman *et al.*, 2003; Pan *et al.*, 2004; Quarmany and Mahjoub, 2005; Pugacheva *et al.*, 2007), but the exact mechanisms involved are not well understood (Plotnikova *et al.*, 2009; Ishikawa and Marshall, 2011). In steady state-length cilia, axonemal disassembly at the tip is balanced by IFT-dependent anterograde transport of tubulin (Marshall and Rosenbaum, 2001; Kozminski *et al.*, 1995; Bhogaraju *et al.*, 2013a). In addition, removal of ciliary membrane by endocytosis at the ciliary pocket (Rattner *et al.*, 2010; Kaplan *et al.*, 2012; Benmerah, 2013) or via budding of ectosomes directly from the ciliary membrane (Wood *et al.*, 2013; Wang *et al.*, 2014) may counterbalance the delivery of membrane vesicles at the ciliary base (see Section ‘The Ciliary Membrane’). These processes are also important for regulating signaling.

Signaling Pathways Coordinated by Cilia

All types of cilia likely function as sensory organelles, which register and convey extracellular signals to control a variety of cellular processes and behavioral responses (Christensen *et al.*, 2007). Specialized sensory cilia are found at dendritic endings on invertebrate neurons, neurons in the vertebrate olfactory epithelium of the nasal cavity, and on photoreceptor cells of vertebrates and certain invertebrates. These include sensilla in the nematode sensory organs that sense chemical, mechanical, osmotic, and thermal cues to control behavioral responses such as feeding, mating, and avoidance responses (Inglis *et al.*, 2007; Bae and Barr, 2008). In some cases, the sensory capacity is maintained by transient receptor potential (TRP) ion channels as well as G-Protein Coupled Receptors (GPCRs), which comprise a large family of 7-pass transmembrane (7TM) receptors that convey signals into a cellular response through the activation of G proteins on the cytoplasmic side of the cilium. A prominent example is that of Opsins, which in the outer segment of rod photoreceptors in the retina convert light signals to nerve impulses via cyclic nucleotide gated ion channels (Pearring *et al.*, 2013).

Sensory Capacity of Primary Cilia

Primary cilia play a unique role in coordinating signaling systems to control cellular processes during development and

in tissue homeostasis (Satir *et al.*, 2010; Goetz and Anderson, 2010). Many types of receptors and other signaling components are enriched in cilia and depend on cilium localization for appropriate function. Examples of signaling pathways coordinated by primary cilia include Hh (Huangfu *et al.*, 2003; Corbit *et al.*, 2005), Wntless/int (Wnt) (Wallingford and Mitchell, 2011; Lienkamp *et al.*, 2012), Notch (Ezratty *et al.*, 2011), RTK (Schneider *et al.*, 2005; Christensen *et al.*, 2012) and Transforming Growth Factor (TGF) β signaling (Clement *et al.*, 2013), as well as signaling through extracellular matrix (ECM) receptors (McGlashan *et al.*, 2006; Seeger-Nukpezah and Golemis, 2012), GPCRs (Berbari *et al.*, 2008; Green and Myktyyn, 2010; Loktev and Jackson, 2013), Purinergic receptors (Masyuk *et al.*, 2008; Wann *et al.*, 2012; Praetorius and Leipziger, 2013) and ion channels (Jones and Nauli, 2012; Figure 4). In this way, primary cilia function as chemo-, mechano-, and osmosensory organelles that regulate cell cycle control as well as polarization, migration, differentiation, size, and homeostasis of cells during organogenesis in embryonic and fetal stages of development as well as in tissue and organ function in the adult (see references above).

Primary cilia and Hedgehog signaling

The Hh signaling pathway is one of the key morphogenic regulators in tissue patterning and organogenesis during animal development (Ingham *et al.*, 2011). Hh signaling was originally discovered in *Drosophila*, where a mutation in this pathway produced a short and ‘spiked’ phenotype of the cuticle of the larvae (Nusslein-Volhard and Wieschaus, 1980). In mammals, Hh signaling is critically linked to the primary cilium, which functions as a cellular switch for the activation and deactivation of the Hh signaling cascade (Rohatgi *et al.*, 2007). In the absence of Hh ligands, the 12TM receptor, Patched 1 localizes to the ciliary membrane, where it blocks the activation of Gli transcription factors in the cilium. Hh signaling is initially turned on by binding of Hh ligands to ciliary Patched 1, which then leaves the ciliary compartment followed by entrance of the 7TM protein, Smoothened, which promotes formation of active versions Gli transcription factors in the cilium for targeted gene transcription in the nucleus. In other ciliary pathways, such as RTK and GPCR signaling, ligands may bind and activate receptors, which directly impinge on secondary messenger components in signal transduction. Finally, receptor-mediated signal transduction may rely on clathrin-dependent endocytosis at the ciliary pocket for activation of Smad transcription factors, such as in TGF β signaling (Clement *et al.*, 2013).

In summary, primary cilia orchestrate the regulation of multiple signaling pathways that control cellular processes during development and in tissue homeostasis. In this scenario, diverse pathways could act in concert in a spatiotemporal manner to regulate specified cellular responses in different cell types and tissues.

Diseases Caused by Defects in Cilia

Owing to the importance of cilia in motility and signal transduction, as well as their wide tissue distribution, mutations in genes required for cilium formation or function

Figure 4 Simplified overview of signaling pathways that are coordinated by primary cilia. Various receptors, ion channels, and other signaling proteins are localized to cilia allowing coordination and integration of diverse signals in time and space to generate an appropriate cellular response. See text for details.

cause a broad range of human diseases called ciliopathies. Most prominently, defects in primary and sensory cilia inevitably lead to a series of developmental disorders and diseases, such as neurodevelopmental disorders, congenital heart disease, obesity, and cystic kidney diseases (Badano *et al.*, 2006; Fliegauf *et al.*, 2007; Hildebrandt *et al.*, 2011; Kenny and Beales, 2014; Tables 2 and 3). Ciliopathies are often rare and pleiotropic with many different tissues affected, and disease phenotypes are often complex with overlapping conditions making precise diagnosis challenging. Furthermore, complex genetic inheritance patterns and genetic modifiers of disease phenotypes have been reported (Lee and Gleeson, 2011;

Beales and Kenny, 2014). A few illustrative examples of ciliopathies will be described briefly below.

Diseases Caused by Defective Motile Cilia

It has been known for many years that defects in motile cilia can cause diseases in humans (Afzelius, 2004). The first human patients with defects in motile cilia were found among males in Denmark and Sweden in the seventies. These patients suffered from a variety of ailments, including infertility, chronic airway infections or situs inversus. Careful examination of immotile sperm cells or bronchial cells from these patients revealed lack

of axonemal dynein arms (Afzelius *et al.*, 1975; Pedersen and Rebbe, 1975; Afzelius, 1976). The disorder, which was named ‘immotile-cilia syndrome’ (Eliasson *et al.*, 1977) showed phenotypical overlap with the previously described Kartagener’s syndrome (Kartagener and Stucki, 1962) and the more recently described syndrome, primary ciliary dyskinesia (PCD; OMIM 244400). PCD is a rare, genetically heterogeneous syndrome with symptoms including infections of the airways, laterality defects, and infertility (Bush *et al.*, 2007; Zariwala *et al.*, 2007). PCD is the most common disorder affecting motile cilia and is usually caused by mutations in ODA genes, although mutations in other genes affecting motility, for example, the gene encoding the nexin-DRC subunit DRC1, have also been reported (Wirschell *et al.*, 2013; Zariwala *et al.*, 2007; Hogg, 2014).

Diseases Caused by Defective Non-Motile Cilia

The first evidence that defects in primary cilia cause disease was provided by studies in *Chlamydomonas* and mouse. In 1994 an insertional mutation was identified in the mouse gene *Tg737* causing a disease phenotype similar to that found in human patients with autosomal recessive polycystic kidney

disease (ARPKD; OMIM 263200) (Moyer *et al.*, 1994). In 2000, Pazour *et al.* demonstrated that the *Chlamydomonas* homolog of Tg737, IFT88, which is part of the IFT-B complex (see Section ‘Intraflagellar Transport’), is required for cilium assembly and that cilia in polycystic kidneys of Tg737 mutant mice are shorter than normal (Pazour *et al.*, 2000). Concomitant studies from the Yoder lab confirmed that Tg737/IFT88 is a ciliary protein required for ciliogenesis (Haycraft *et al.*, 2001; Taulman *et al.*, 2001).

Barr and Sternberg had previously shown that products of the *C. elegans* homologs of the mammalian autosomal dominant polycystic kidney disease (ADPKD) genes, PKD1 and PKD2, are localized to non-motile cilia on male cephalic neurons (Barr and Sternberg, 1999). These studies indicated for the first time that correct assembly and maintenance of cilia are required for appropriate functioning of the kidney and that malfunctions in this organelle can lead to kidney cysts similar to those found in patients with ARPKD. These studies also spurred an intense interest in primary cilia, and lead a virtual boom in research in this organelle.

ARPKD is mainly caused by mutations in the *PKHD1* gene, whose protein product Fibrocystin localizes to cilia of

Table 3 List of symptoms commonly associated with ciliopathies

Symptom
Anosmia
Brain anomalies
Cancer
Cognitive disorders
Diabetes
Hearing loss
Heart defects
Hydrocephalus
Hypertension
Infertility
Kidney cysts
Lateral defects
Liver cysts
Obesity
Pancreas cysts
Respiratory disorders
Retinal degeneration
Skeletal malformations

kidney-derived cells (Ward *et al.*, 2002, 2003). ADPKD is an ARPKD-related disease in which the form of kidneys and cysts differ significantly from those of ARPKD patients; a well-established criterium for diagnosis (Bergmann, 2014). Mutations in *PKD1* and *PKD2* account for the majority of ADPKD cases (Rossetti *et al.*, 2007). The population prevalence varies between 1:400 and 1:1000 affected (Sandford, 2014).

Another prominent ciliopathy is BBS (OMIM 209900), a pleiotropic and genetically heterogeneous disorder with at least 16 causative genes found to date (Forsythe and Beales, 2013). Many of the encoded BBS proteins are involved in selective transport of membrane proteins to and from the ciliary compartment (Nachury *et al.*, 2007; Loktev *et al.*, 2008; Lechtreck *et al.*, 2009; Wei *et al.*, 2012). Mutations in *BBS* genes lead to defective transport of several membrane proteins to cilia affecting signaling and homeostasis of many different tissues (Zaghloul and Katsanis, 2009). Patients with BBS suffer from primary features including retinal degeneration, polydactyly, mental retardation, truncal obesity, and genital and renal anomalies as well as secondary features including speech disorders, developmental delay, hearing loss, and lateral defects (Tobin and Beales, 2007).

Skeletal Muscle

B Cadot, Sorbonne Universités UPMC, Paris Cedex, France

The skeletal muscle is a highly differentiated tissue responsible for force generation involved in body movements. Coordination of different muscles is important for posture of the body, movement of arms and legs, and for fine movements of the fingers. Such activities are achieved by the connection of the muscle with the skeleton under the control of motor neurons. Muscle contraction is achieved by the contraction of individual muscle cells, known as myofibers, which are highly specialized long cells containing multiple nuclei that are distributed along the periphery of the cell, right next to the plasma membrane (sarcolemma).

Myofibers are the cells in the human body with the largest volume. Each myofiber is connected to a single neuron forming a neuromuscular synapse. Individual myofibers are surrounded by a basal lamina (endomysium). A small number of muscle stem cells (satellite cells) are found between the myofiber and basal lamina. Myofibers are grouped in muscle bundles surrounded by a connective tissue (perimysium) which together form a muscle. The extremities of each muscle are connected to the skeleton by tendons. All these structures lead to the translation of force generated by individual myofibers into the movement of the skeleton.

Myofibers are formed by the fusion of mononucleated myoblasts during embryogenesis in a process involving a complex change of the gene expression program of cells (Bentzinger *et al.*, 2012). In adult muscle, satellite cells can proliferate and give rise to mononucleated myoblasts that are able to repair damaged myofibers and form *de novo* myofibers. The proliferation of satellite cells is asymmetric so that a small number of cells retain their stem cell capability and give rise to satellite cells of the newly formed myofibers (Tajbakhsh, 2009).

Sarcomeres Are the Basic Unit of Contraction

Skeletal muscles exhibit regular striations along their length with about 2 μm spacing. These striations are formed by sarcomeres, the basic unit of contraction in the myofiber (Huxley, 1969). Sarcomeres are composed of multiple thick and thin filaments that overlap and each sarcomere is delimited by the Z disk (or Z line) (Cheng and Deatherage, 1989). Thick filaments are made of myosin and occupy a more central region of the sarcomere (the A band) whereas thin filaments are made of actin that is anchored to the Z disk. Different regions of the sarcomere have been named as bands due to their appearance when observed with polarized light (Figure 1). The region of thin filaments that does not overlap with the thick filaments is called the I band. The Z disk is in the middle of the I band.

Thick filaments of myosin are bipolar. Myosin tails form the core of the thick filament and point away from the extremities of the filament, whereas myosin heads stick out of the filament. The middle of the thick filament is called the M

line, which is also the axis of symmetry of the thick filament and the sarcomere (Agarkova and Perriard, 2005).

Thin filaments of actin are unipolarized; the plus (barbed) end of the filament is anchored to the Z disk and the minus (pointed) end is pointing to the middle of the sarcomere, the H band.

The region where myosin and actin filaments overlap (AI zone), one myosin filament is surrounded by six actin filaments and each actin filament is surrounded by two or three myosin filaments, depending on the species (Milligan and Flicker, 1987).

Multiple regulatory proteins bound to myosin and actin filaments are required for the structure and function of sarcomeres (Table 1). At least three gigantic proteins, titin, nebulin, and obscurin, play an important role on the function of sarcomeres. Each nebulin protein extends along the length of the actin filaments, from the Z disk toward the middle of the sarcomere and has a role stabilizing actin filaments. Titin (probably the biggest protein in humans) extends from the Z disk to the M line. Titin is an elastic protein and acts like a spring to keep the thick filaments in the center of the sarcomere. Obscurin is involved in the anchoring of sarcomeres to the sarcoplasmic reticulum (SR) and costameres (see below) (Gokhin and Fowler, 2013; Pappas *et al.*, 2011; Randazzo *et al.*, 2013; Tskhovrebova and Trinick, 2003).

Sarcomeric components are very dynamic, contrary to what we would expect from such a highly organized structure. For instance, actin, tropomyosin, and multiple Z disk proteins can incorporate into matured sarcomeres within minutes without any changes in sarcomere structure (Ono, 2010; Sanger *et al.*, 2010).

Sarcomeres are connected to the sarcolemma by the costamere, a protein complex. Costameres physically link the sarcolemma to the Z disk of the sarcomeres that are located right under the sarcolemma. In addition, costameres also link the sarcolemma to the extracellular matrix under the basal lamina (Ervasti, 2003). Costamere integrity is important for the transduction of force generated by the sarcomere to the sarcolemma and basal lamina, resulting in the contraction of the muscle (Rybakova *et al.*, 2000).

Sarcomere Contraction Is Driven by Sliding of Myosin and Actin Filaments

During muscle contraction, the length of myosin and actin filaments does not change. What changes is the distance between the extremities of the myosin filaments and the Z disks (the I band). Thus, during muscle contraction, the actin filaments move along the myosin filaments. This occurs because myosin heads bind to and move on actin filaments. Because both filaments are polarized, and myosin moves toward the barbed end of actin (at the Z disk), the movement of myosin

Figure 1 Sarcomere structure in resting and contracting states. Sarcomeres are mainly composed of actin (gray) and myosin (red) filaments. Nebulin (yellow) extends along the actin filament and titin (dark blue) stretches all the way from the Z disk to the M line. α -actinin (black) and CapZ (light blue) are Z disk components. Tropomyosin (green) extends along the actin filament and tropomodulin (purple) is at the extremity of the actin filament, the barbed end. In a contracted sarcomere, the length of the actin and myosin filaments does not change. Contraction occurs due to the sliding of actin filaments on myosin filaments. Therefore the AI zone increases whereas I band decreases, and the A band remains the same length. In contracted sarcomeres, titin is also shorter due to its function of spring to keep the integrity of the sarcomere.

Table 1 Sarcomere components

Name	Localization	Function	Disease
Actin	Actin filaments	Filament formation and sliding	Nemaline myopathy (Romero <i>et al.</i> , 2013)
Myosin	Myosin filaments	Filament formation and sliding	
C-protein	Myosin filaments	Stabilization	
M-protein	M line	Stabilization of myosin at M line	
α -actinin	Z disk	Connect actin filaments to Z disk	Desmin myopathy (Goldfarb <i>et al.</i> , 2004)
CapZ	Z disk	Caps actin filament barbed ends	
Desmin	Z disk	Stabilization	
Myotilin	Z disk	Binds to α -actinin	
Tropomyosin	Actin filaments	Prevents binding of myosin to actin	Nemaline myopathy (Vindin and Gunning, 2013)
Troponin I	Actin filaments	Inhibitory subunit of troponin	
Troponin T	Actin filaments	Tropomyosin-binding subunit of troponin	Nemaline myopathy (Kee and Hardeman, 2008)
Troponin C	Actin filaments	Calcium-binding subunit of troponin C	
Tropomodulin	Actin filaments	Binds to tropomyosin and caps actin filament pointed ends	Muscular dystrophy (Selcen and Carpén, 2008)
ZASP	Z disk	Stabilizes Z disk	
Nebulin	Actin filaments	Stabilizes actin filaments	
Titin	Actin and myosin filaments	Muscle elasticity	
Leiomodin3	Actin filaments	Actin nucleator	Nemaline myopathy (Chereau <i>et al.</i> , 2008; Yuen <i>et al.</i> , 2014)
Obscurin	M line and Z disk	Connect sarcomeres to sarcoplasmic reticulum and costameres	

heads connected to the actin filaments results in the sliding of these filaments and shortening of the sarcomere (distance between Z disks). The force produced by the sliding is proportional to the overlap between the myosin and actin filaments determined by the length of the sarcomere (Cooke, 1986; Gordon *et al.*, 1966).

Myosin movement is powered by the hydrolysis of ATP to ADP + Pi and each cycle of ATP binding and hydrolysis results in one stroke of the myosin head (Figure 2).

This process occurs in four steps. When ATP binds to myosin, myosin heads detach from actin filaments (step 1). Next, ATP is hydrolyzed to ADP + Pi (that remain bound to myosin) and results in the rotation of myosin heads to a position perpendicular to actin filaments (step 2). Next, in the presence of Ca^{++} , actin filament binds to the myosin head resulting in the release of Pi from myosin (step 3). Finally, the myosin head moves to about 45° of the actin filament, resulting in the movement of the actin filament and release of ADP (step 4). Step 4 is followed by step 1 with the binding of a new ATP molecule (Eisenberg and Hill, 1985; Geeves and Holmes, 1999; Irving, 1985).

A stroke of myosin that occurs during one cycle results in about 7 nm displacement of actin filament. However, each sarcomere contracts around 2000 nm. In order to achieve such a long range of movement, the detachment of myosin from actin and the existence of multiple myosin–actin binding sites that are in different stages of the ATP hydrolysis cycle is essential. This way, myosin filaments move on actin filaments like the legs of a walking centipede instead of the synchronized rows of a rowing galley.

When muscles are depleted of ATP, they become stiff and rigid, and this condition is named rigor. The best example of rigor is observed shortly after death. In rigor, the depletion of ATP and increase of cytosolic Ca^{++} concentration results in the tight binding of actin filaments to myosin heads preventing sliding of these filaments and causing muscle rigidity.

Calcium Release from the SR Activates Contraction

Muscle contraction is controlled by the motor neurons axons that form synapses with myofibers called the neuromuscular junction. Action potentials on the axons trigger the fusion of acetylcholine-containing synaptic vesicles with the plasma membrane, resulting in the release of acetylcholine into the cleft between the axon and the myofiber. Acetylcholine binds to the acetylcholine receptors, cation channels, leading to the opening of these channels and the generation of a new action potential in the myofiber plasma membrane (the sarcolemma).

Muscle contraction is triggered by the increase of cytosolic Ca^{++} concentration. Therefore, as long as the Ca^{++} concentration is high in the cytosol, and there is ATP, the myosin–actin connection and movement will continue to cycle and the muscle will remain contracted (Goldman *et al.*, 1982).

Sarcomeres form repetitive structures along the myofiber that are named myofibrils. Each myofibril is encircled by smooth endoplasmic reticulum, named SR that is the main Ca^{++} reservoir of the myofiber (Figure 3).

The SR network is interrupted by T-tubules, which are invaginations of the sarcolemma. T-tubules can be found near the Z disk or the A–I junction, depending on the organism and muscle type. The region of the SR that is next to each T-tubule is called terminal cisterna. A T-tubule is surrounded by two SR terminal cisternae forming a triad (Table 2). Triads play an important role on the control of muscle contraction. The T-tubule has voltage-sensitive Ca^{++} channels named dihydropyridine receptors (DHPR) that are physically connected to Ca^{++} channels in the SR named ryanodine receptor (Table 2; Franzini-Armstrong *et al.*, 1998). Depolarization of the T-tubule membrane due to the action potential generated at the neuromuscular synapse causes a conformation change of the DHPRs at the T-tubule. DHPRs directly induce the opening

Figure 2 ATP hydrolysis and myosin stroke cycle. Step 1 – ATP binding to myosin and detachment from actin. Step 2 – ATP hydrolysis into ADP + Pi and myosin rotation. Step 3 – Binding of myosin to actin and Pi release. Step 4 – Myosin head stroke and ADP release.

Figure 3 Organization of SR and T-tubules in skeletal muscle. Each myofiber is formed by multiple myofibrils (brown and red) that are surrounded by SR (light blue). The SR is interrupted by T-tubules (light green) that are invaginations of the sarcolemma, and therefore their lumen communicates with the extracellular space.

Table 2 Triad components

Name	Localization	Function	Disease
BIN1/ amphiphysin	T-tubule	Scaffolding	Centronuclear myopathy (Jungbluth <i>et al.</i> , 2008)
DHPR	T-tubule	Depolarization sensor	Malignant hyperthermia (Monnier <i>et al.</i> , 1997)
RyR	SR	Ca ⁺⁺ channel	Congenital muscular dystrophy (Bönnemann <i>et al.</i> , 2014)
Triadin	SR	Scaffolding	
Junctophilin	SR	Connect SR to T-tubule	
Ca ⁺⁺ ATPase	SR	Pumps Ca ⁺⁺ from cytosol into SR	Brody myopathy (Odermatt <i>et al.</i> , 1996)

of the Ca⁺⁺ channels of the ryanodine receptor at the SR which results in the release of Ca⁺⁺ from the SR into the cytosol. The increase of cytosolic Ca⁺⁺ triggers sarcomere contraction (Ridgway and Ashley, 1967). This process is called excitation-contraction coupling (Ríos *et al.*, 1992). Because the depolarization along the sarcolemma and T-tubules occurs in milliseconds, every sarcomere in a myofiber contracts simultaneously. When depolarization stops, Ca⁺⁺ ATPases in the SR pump Ca⁺⁺ back to the SR resulting in the decrease of cytosolic Ca⁺⁺ calcium concentration and muscle relaxation (Pellegrino and Franzini-Armstrong, 1969).

Increase of cytosolic Ca⁺⁺ concentration allows the binding of myosin heads to the actin filaments during step 3 of the cycle of ATP hydrolysis and myosin stroke. This process is mediated by tropomyosin and troponin, which are bound to actin filaments. When cytosolic Ca⁺⁺ concentration is low, tropomyosin and troponin prevent the binding of actin filaments to myosin heads. Tropomyosin binds laterally to actin filaments forming a long filament around the actin filament. Troponin is composed of three subunits: Troponin I, Troponin T, and Troponin C. When cytosolic Ca⁺⁺ concentration increases, it binds to Troponin C and results in a conformational change of Troponin I that leads to a shift of tropomyosin relative to actin filament (Figure 4).

The exposed actin filament surface is then more likely to bind to ADP-Pi myosin which is followed by Pi release and myosin movement. The binding of the first myosin head to actin shifts the tropomyosin filament beyond the original binding sites facilitating the binding of adjacent myosin heads to actin filaments (Phillips *et al.*, 1986).

Muscles can contract different lengths and at different speeds and forces. Such regulation does not occur at the level of each individual myofiber since each fiber is either contracted or relaxed. Instead this regulation occurs at the level of the motor neurons that are connected to the myofibers. Motor neurons are connected to a myofiber by the neuromuscular junction, also known as the neuromuscular synapse. This synapse works as a neuron-neuron synapse where the action potential of an axon is transferred to a downstream neurite. At the neuromuscular junction, the myofiber is downstream of the axon, and the action potential of the axon results in the depolarization of sarcolemma that quickly travels along the all sarcolemma and T-tubules leading to myofiber contraction. Each motor neuron is connected to one or more myofibers, forming a motor unit (English and Wolf, 1982). However, each myofiber has only one neuromuscular junction connected to a single motor neuron. Therefore, muscle length and speed is regulated by the number of motor units that are

Figure 4 Conformation change of tropomyosin and troponin relative to actin filaments upon increase of cytosolic Ca^{++} . In low cytosolic Ca^{++} (pink) concentration, troponin (blue) and tropomyosin (green) occupies the myosin binding side of each actin subunit along the actin filaments. When cytosolic Ca^{++} concentration increases, the binding of Ca^{++} to troponin C leads to the shifting of tropomyosin relative to the actin filament, exposing myosin binding sites and allowing the binding of myosin heads to actin.

Table 3 Costamere components

Name	Localization	Function	Disease
Dystrophin	Cytosol	Connect actin to sarcolemma	Muscular dystrophy (Rahimov and Kunkel, 2013)
β -Dystroglycan	Sarcolemma	Connects sarcolemma to extracellular matrix	Limb-girdle muscular dystrophy (Rahimov and Kunkel, 2013)
α -, β -, and γ - Sarcoglycan	Sarcolemma	Connects sarcolemma to extracellular matrix	Limb-girdle muscular dystrophy (Rahimov and Kunkel, 2013)
Integrin $\alpha 7$	Extracellular	Extracellular matrix structure	Congenital myopathy (Hayashi <i>et al.</i> , 1998)
Collagen VI	Extracellular	Extracellular matrix structure	Bethlem myopathy (Briñas <i>et al.</i> , 2010)

activated. The more the motor units are activated, the higher and faster is the contraction. On the other hand, the rate of stimulation by the motor neuron controls the force produced by each myofiber in a motor unit.

Muscle Disorders Associated with Skeletal Muscle

Multiple genetic disorders have been identified to be caused by mutation in genes encoding proteins from the sarcomeres, costameres, extracellular matrix, triads, and nuclear envelope in the skeletal muscle (Tables 1–3). The first mutation to be identified was a protein from the costamere that was named dystrophin, since it was found in a patient with Duchenne’s muscular dystrophy. Mutations in dystrophin and other costameric proteins lead to the weakness of the connection between the sarcomere and the sarcolemma which results in myofiber damage during muscle activity (Rahimov and Kunkel, 2013). Due to this damage, the muscle of these patients is constantly undergoing regeneration. However, with age, the ability for the muscle to regenerate is lost, leading to muscle impairment. Patients with Duchenne muscular dystrophy start losing their locomotion capability and the premature cause of death is mostly caused by failure of respiratory muscles.

Filopodia and Lamellipodia

TM Svitkina, University of Pennsylvania, Philadelphia, PA, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

Barbed end/pointed end Opposite ends of intrinsically polar actin filaments with the barbed end (plus end) exhibiting more rapid dynamics than the pointed end (minus end).

Filopodia Thin, filamentous protrusions extending from the cell surface and responsible for probing the surrounding environment and reaching distant targets.

Lamellipodia Broad and flat sheet-like cellular protrusions.

Nucleation Initial slow phase of polymerization that involves thermodynamically unfavorable clustering of first few monomers. This cluster, or nucleus, then undergoes elongation by incorporating additional subunits.

Ruffles Cellular protrusions formed by uplifting of lamellipodia.

Treadmilling Phenomenon of actin dynamics at which actin monomers incorporate at the barbed end of the actin filament and dissociate from its pointed end at the same ambient concentration of actin monomers.

Introduction

Individual cell migration consists of repeating cycles of protrusion and attachment of the cell front followed by detachment and retraction of the rear. Protrusion of the leading edge is an important component of cell locomotion. It typically occurs in the form of planar protrusions termed lamellipodia or slender protrusions termed filopodia (Figure 1). Lamellipodia can generate large pushing forces and carry the main load of propelling the cell front, whereas filopodia can extend far beyond the cell edge and reach or sense distant targets. A balance between filopodial and lamellipodial modes of protrusion varies broadly among cell types and may reflect relative needs of the cell to undergo fast locomotion versus precise navigation (Figure 2).

Figure 1 Organization of actin filaments at the leading edge of a fibroblast-like mouse melanoma cell visualized by transmission electron microscopy after detergent extraction, chemical fixation, critical point drying, and rotary shadowing of cultured cells with platinum and carbon. Modified from Yang, C., Czech, L., Gerboth, S., *et al.*, 2007. Novel roles of formin mDia2 in lamellipodia and filopodia formation in motile cells. *PLoS Biology* 5, e317.

The molecular machinery driving cell locomotion converges on the actin cytoskeleton, a complex system of actin filaments and numerous accessory proteins regulating actin filament dynamics and spatial organization. Actin cytoskeleton is the major force-generating machinery in the cell that can produce pushing, pulling, and resistance forces by forming various higher order ensembles, networks and bundles, adapted to specific tasks. Dynamic properties of the actin cytoskeleton allow a cell to quickly redesign actin structures according to its changing needs.

Both lamellipodia and filopodia generate pushing force using the same molecular strategy, coordinated polymerization of multiple interconnected actin filaments. Acting as a cohort, actin filaments can achieve necessary stiffness to produce large forces. Filopodia and lamellipodia coordinate polymerization of multiple filaments in different ways. Specifically, actin filaments form parallel bundles in filopodia, but branching networks in lamellipodia. Accordingly, actin polymerization in these protrusions is regulated by distinct, but overlapping, sets of accessory proteins.

General Principles of Actin Polymerization-Driven Protrusion

The concept that actin polymerization alone can produce protrusive force has emerged from a series of studies of the acrosomal reaction in invertebrate sperm by Tilney and coworkers (Tilney, 1975). Although this discovery was made in a specialized cellular system, the concept has general significance and applies to lamellipodia and filopodia. The directionality of pushing force originates from intrinsic polarity of the actin filament, which is further amplified by hydrolysis of actin-bound ATP accompanying actin polymerization. Due to structural and biochemical differences, one end of the actin filament ('barbed' or 'plus' end) can grow in the same conditions, in which the other ('pointed' or 'minus') end shrinks (Figure 3), the process being called treadmilling. In lamellipodia and filopodia, actin filaments are oriented with their barbed ends facing the plasma membrane (Small *et al.*, 1978).

Figure 2 Schematics of actin filament organization at the leading edge of different cell types. Fibroblasts display a mixture of lamellipodia, filopodia, microspikes, and retraction fibers. They also contain contractile actin-myosin II bundles (stress fibers in the cell interior). Leading edge of neuronal growth cones is especially rich in filopodia with small lamellipodia located between filopodia. Fish or frog epidermal keratocytes typically express only lamellipodia. Modified from Svitkina, T., 2013. Actin organization. In: Lennarz, W.J., Daniel Lane, M. (Eds.), *Encyclopedia of Biological Chemistry*. Waltham, MA: Academic Press, pp. 27–35.

Figure 3 Actin filament treadmilling. Intrinsic structural polarity and polymerization-linked ATP hydrolysis allows an actin filament to undergo treadmilling by assembling subunits at the barbed end (right) and releasing subunits from the pointed end (left). This dynamic behavior is accelerated by profilin and ADF/cofilin. Modified from Svitkina, T., 2013. Actin organization. In: Lennarz, W.J., Daniel Lane, M. (Eds.), *Encyclopedia of Biological Chemistry*. Waltham, MA: Academic Press, pp. 27–35.

Polymerizing barbed ends push onto the membrane, whereas actin filament disassembly occurs closer to the pointed ends. Balanced rates of polymerization and depolymerization would allow a cell to maintain steady-state actin turnover. Intrinsic

treadmilling of actin filaments observed biochemically is too slow to account for fast rates of leading edge protrusion in living cells (Pollard and Mooseker, 1981), but can be accelerated by accessory proteins (Carlier *et al.*, 1997). Key

Figure 4 Formins (a) and Ena/VASPs (b) promote barbed end elongation. The mechanism of action of these unrelated proteins involves processive tracking and anti-capping protection of the growing end using actin-binding domains, recruitment of profilin-actin complexes using profilin-binding proline-rich regions, and anchorage to the plasma membrane using membrane-binding domains.

regulators of facilitated actin turnover are common for filopodia and lamellipodia (Figures 3 and 4).

Profilin is a small actin monomer binding protein, which functions to ensure that monomer addition occurs specifically at the barbed end of preexisting filaments (Tilney *et al.*, 1983). Profilin binds the barbed end surface of an actin monomer thereby precluding monomer interaction with the pointed end of other monomers or polymers (Figure 3). As a result, both spontaneous filament nucleation and elongation of filaments at their pointed ends are suppressed by profilin (Yarmola and Bubb, 2009). After addition of a profilin-actin complex into a filament barbed end, profilin dissociates leaving the barbed end free to assemble additional subunits. Profilin also functions as a nucleotide exchange factor by loading actin monomers with ATP.

Proteins of the actin depolymerizing factor (ADF)/cofilin family sever actin filaments and thus facilitate their depolymerization by increasing the number of disassembling ends (Bernstein and Bamburg, 2010; Figure 3). ADF/cofilins can bind both actin monomers and filaments with preference for ADP-containing actin subunits in either case (Carlier *et al.*,

1997). By cooperatively binding to the side of the actin filament, ADF/cofilins overtwist the actin filament helix and destabilize subunit-subunit interaction at the boundary between cofilin-loaded and cofilin-free actin filament segments. Higher affinity for ADP-containing actin subunits allows ADF/cofilin to preferentially accelerate depolymerization of an older part of the actin filament located closer to its pointed end.

Two unrelated protein families, Ena/VASP and formins, use analogous mechanisms to accelerate barbed end elongation and extend duration of elongation (Dominguez, 2010). Both formins and Ena/VASPs bind barbed ends and allow for addition of new actin subunits to the barbed end without dissociating from the end, a process called processive tracking (Figure 4). Using actin-binding or profilin-binding domains, Ena/VASPs and formins increase the local concentration of polymerizable monomers near the growing barbed end and thus accelerate its elongation. Membrane-binding domains within these proteins allow them to keep elongating ends near the membrane to increase efficiency of pushing. Formins and Ena/VASPs also prevent binding of

capping proteins, which could terminate barbed end elongation.

Filopodia

Definition

Filamentous pseudopodia had been known since the mid-1800s, when the morphologies of protrusive organelles characteristic of various Protozoa were classified. The term 'filopodia' was introduced to define these long and slender cellular protrusions. With an advent of cell culture (Harrison, 1907), filopodia were also documented in mammalian cells. At present, this term is variably used to designate a broad class of cellular protrusions characterized by a high length-to-width ratio, as introduced originally, or to refer to a best-studied class of filopodia at the leading edge of migrating animal cells.

Behavior and Functions

Filopodia are found in many different cell types and broadly vary in morphology. They often display not only protrusive, retractile, and sweeping motility, but also exist as stationary anchored cellular extensions. Because of their elongated geometry, filopodia are well designed to function as 'sensors,' which can reach, detect, and grasp distant targets. Accordingly, filopodia are believed to guide cell locomotion during normal tissue morphogenesis or cancer metastasis by recognizing adhesive surfaces and making initial contacts with the extracellular matrix. Filopodia of neuronal growth cones are thought to recognize attractive and repulsive cues and direct the axon to its destination (Drees and Gertler, 2008), whereas filopodia of endothelial tip cells appear to guide the growth of blood vessels during angiogenesis (De Smet *et al.*, 2009). Filopodia can also establish communication with other cells by finding a proper cellular partner and making initial contacts. For example, filopodial bridges formed between contacting endothelial (Hoelzle and Svitkina, 2012) or epithelial cells (Vasioukhin *et al.*, 2000) are important for subsequent formation of adherens junctions. In neurons, dendritic filopodia establish initial excitatory synapses with axons and then differentiate into dendritic spines (Bourne and Harris, 2008). Filopodia can also capture various particles, such as pathogens, for subsequent internalization (Romero *et al.*, 2011).

Structure and Dynamics

Filopodia that are formed at the leading edge of migrating cells, such as fibroblasts, or cells undergoing dramatic shape changes, such as neurons, are best characterized structurally and dynamically. These filopodia contain an actin filament bundle, in which individual filaments span the entire length of the filopodium and are uniformly oriented with barbed ends toward the filopodial tip (Small *et al.*, 1978; Figure 5). During protrusion, actin subunits are added at the filopodium tip, move away from the tip as part of the filament lattice, and are released at the rear of filopodium, thus undergoing treadmilling (Wang, 1985). Introduction of fiducial marks into the actin filament bundle in filopodia demonstrated that while the

Figure 5 Actin filament organization in a filopodium at the leading edge of a mouse melanoma cell. Boxed region is enlarged in the right panel and shows long parallel actin filaments. Transmission electron microscopy of the cell after detergent extraction, chemical fixation, critical point drying, and rotary shadowing with platinum and carbon. Modified from Svitkina, T., 2013. Actin organization. In: Lennarz, W.J., Daniel Lane, M. (Eds.), *Encyclopedia of Biological Chemistry*. Waltham, MA: Academic Press, pp. 27–35.

filopodial tip grows forward the entire bundle slides backward (Mallavarapu and Mitchison, 1999). A balance between rates of protrusion and retrograde flow varies among individual filopodia and can be controlled, at least in part, by the strength of linkage(s) between the filopodial cytoskeleton and the substrate (Suter *et al.*, 1998).

Other cellular structures, such as microspikes and retraction fibers (Figure 1), are similar to leading edge filopodia in structural organization. Like filopodia, both microspikes and retraction fibers contain a parallel bundle of actin filaments. However, microspikes in contrast to filopodia do not significantly extend beyond the cell leading edge, but protrude at the same rate as the surrounding cell edge. Retraction fibers have an elongated narrow shape, like filopodia, but are formed in the course of cell edge retraction, rather than via their own protrusion. Yet, some retraction fibers can elongate at the tip, thus sharing dynamic features with filopodia. Similar structure and dynamics, as well as frequent interconversion between these organelles, indicate that filopodia, microspikes, and retraction fibers are related structures (Svitkina *et al.*, 2003).

Parallel actin filament bundles similar to those in filopodia are also present in other cylindrical cell surface extensions, such as brush border microvilli in intestinal epithelium (Mooseker and Tilney, 1975) and hair cell stereocilia in the inner ear (Tilney *et al.*, 1980). Unlike filopodia, microvilli and stereocilia maintain a constant length and exhibit very slow

(microvilli) (Tyska and Mooseker, 2002) or negligible (stereocilia) actin dynamics (Zhang *et al.*, 2012).

Notably, not all cylindrical membrane protrusions contain parallel actin bundles. It is becoming increasingly clear that filopodia defined purely by shape significantly vary in their structure, dynamics, and molecular composition. For example, dendritic filopodia of neuronal cells, as well as narrow elongated necks of dendritic spines, contain loosely cross-linked actin networks, in which a small fraction of actin filaments is oriented with their barbed end away from the tip of the protrusion (Korobova and Svitkina, 2010). Some experimentally induced filopodia also contain relatively sparse actin filaments having variable lengths and mutual positions (Yang *et al.*, 2009).

Molecular Machinery for Filopodial Protrusion

Filopodia protrusion involves coordinated changes in the membrane and the actin cytoskeleton. Actin polymerization and membrane deformation during filopodia protrusion are regulated by distinct, but interacting molecular machineries.

Actin cytoskeleton

Formation of tight bundles of uniformly oriented and synchronously polymerizing actin filaments is a key strategy used by leading edge filopodia to generate pushing force. The dynamics of the actin cytoskeleton during steady state filopodial protrusion is described by the treadmilling model. It states that actin filaments within the filopodial bundle continuously elongate at their distal barbed ends and depolymerize at the rear close to the pointed ends (Mallavarapu and Mitchison, 1999; Wang, 1985). Various aspects of actin dynamics in filopodia are regulated by proteins controlling actin filament elongation, cross-linking, and disassembly (Figure 6).

Elongation of filopodial filaments in the presence of abundant capping proteins in the cytoplasm is largely controlled by proteins of Ena/VASP or formin families, although relative contribution of these protein families varies among cell types. Ena/VASP proteins are particularly important for formation of filopodia in neuronal growth cones (Lebrand *et al.*, 2004), but share this function with formins in other cell types (Homem and Peifer, 2009). Consistent with their ability to processively track growing barbed ends, Ena/VASP proteins and specific formins are enriched at filopodial tips and promote actin filament elongation *in vivo* (Svitkina *et al.*, 2003; Yang *et al.*, 2007). Since formins are also actin nucleators (Pruyne *et al.*, 2002; Sagot *et al.*, 2002), in principle, they may contribute to filopodia formation in this capacity. However, formins poorly nucleate actin filaments from profilin-actin complexes, the main polymerizable actin species in the cytoplasm, and need to cooperate with other actin filament nucleators, such as the Arp2/3 complex (Svitkina *et al.*, 2003; Yang *et al.*, 2007), adenomatous polyposis coli (APC) (Okada *et al.*, 2010), or Spire (Bosch *et al.*, 2007; Quinlan *et al.*, 2007) to overcome this barrier. Formins and Ena/VASPs also function to processively anchor growing actin filament barbed ends to the plasma membrane using membrane-binding domains.

Filopodium geometry is unfavorable for the delivery of building components to the tip by simple diffusion (Mogilner

Figure 6 Schematics of the filopodial molecular machinery. Actin filaments are oriented with barbed ends toward the filopodial tip (top). They are bundled by fascin and laterally attached to the plasma membrane by ERM proteins. Formin and/or Ena/VASP proteins associate with the barbed ends, promote their elongation, and anchor them to the membrane at the filopodial tip. Myosin X travels along actin filaments to the filopodial tip. I-BAR domain-containing proteins, such as IRSp53, help maintaining the tubular shape of the plasma membrane. Modified from Svitkina, T., 2013. Actin organization. In: Lennarz, W.J., Daniel Lane, M. (Eds.), *Encyclopedia of Biological Chemistry*. Waltham, MA: Academic Press, pp. 27–35.

and Rubinstein, 2005). Unconventional myosin X, which plays an important role in filopodia elongation (Berg and Cheney, 2002) is believed to use its motor activity to deliver cytoplasmic components, such as Ena/VASP and surface receptors, to filopodial tips. Enrichment of myosin X at filopodial tips suggests that it may have additional roles in promoting filopodium protrusion.

Long actin filaments individually are not efficient at pushing, as they tend to buckle. To produce efficient pushing, filopodial filaments are immobilized by cross-linking along their length, which increases their collective stiffness. The major actin filament cross-linker in filopodia is fascin (Vignjevic *et al.*, 2006). It was first isolated from sea urchin eggs (Kane, 1975) and subsequently shown to bundle actin filaments in filopodia of sea urchin coelomocytes and mammalian cells. Fascin is a bivalent monomeric protein (Sedeh *et al.*, 2010) that *in vitro* induces needle-shaped bundles of actin filaments characterized by high rigidity. In cells, fascin allows actin filaments to overcome membrane resistance and avoid buckling during filopodial protrusion (Vignjevic *et al.*, 2006). Fascin undergoes fast turnover within filopodial bundles, which may help to release stresses and torques within the bundle as it assembles. Other monomeric actin cross-linkers,

such as fimbrin, espin, and villin, form parallel bundles in other cylindrical protrusions, such as microvilli and stereocilia.

Depolymerization of filopodial filaments is accelerated by their severing. Two actin filament severing proteins, ADF/cofilin (Breitsprecher *et al.*, 2011; Gehler *et al.*, 2004) and gelsolin (Lu *et al.*, 1997), play a role in this process. Although ADF/cofilin is absent in most filopodia (Svitkina and Borisy, 1999), it accumulates in stationary and retracting filopodia and promotes their disassembly (Breitsprecher *et al.*, 2011). Conventional myosin II, which is typically involved in contractile cellular activities, also contributes to generation of additional filament ends by breaking proximal regions of filopodial bundles (Medeiros *et al.*, 2006).

Many proteins besides Ena/VASPs, formins, and myosin X are associated with filopodial tips, where they form a morphologically recognizable tip complex (Svitkina *et al.*, 2003). Although functions of all these proteins are not yet fully established, talin (DePasquale and Izzard, 1991) and integrins (Wu *et al.*, 1996) may be needed to initiate adhesions with a suitable surface, whereas N-WASP, CR16 (Ho *et al.*, 2001), and Abi proteins (Stradal *et al.*, 2001), as well as some signaling molecules, like Vav (Kranewitter *et al.*, 2001), may function to trigger cellular responses when a filopodium finds an appropriate target.

Some proteins are found in proximal filopodial regions. A cross-linking protein α -actinin is found at the base of filopodia (Vignjevic *et al.*, 2006), where it may integrate filopodial bundles into the cytoplasmic actin cytoskeleton. Myosin II also frequently interacts with the cytoplasmic root of filopodial bundles (Bridgman and Dailey, 1989). By pulling on filopodial actin filaments, myosin II can contribute to their retrograde flow and reinforce adhesions for efficient protrusion.

Lateral binding of filopodial bundles to the plasma membrane helps to maintain the shape of filopodia. Proteins of ezrin–radixin–moesin (ERM) family, which can bind both actin filaments and the membrane, are likely candidates for this role (Bretscher *et al.*, 2002). ERM proteins localize to filopodia and promote their formation in some systems.

Membrane deformation

Changes in the membrane geometry accompanying filopodial protrusion are powered in part by the membrane-binding and deforming proteins, not only by cytoskeleton activity. Most of these proteins contain one of two related protein domains, I-BAR (Zhao *et al.*, 2011) or IF-BAR (Carlson *et al.*, 2011), which bind membrane lipids via their convex surface and cause negative membrane curvature (away from the cytoplasm). When expressed in cells, an isolated I-BAR domain from IRSp53 induces filopodia-like protrusions (Yamagishi *et al.*, 2004). These protrusions initially represent empty membrane tubes, but are subsequently filled with actin filaments (Yang *et al.*, 2009). In a physiological situation, IRSp53 upon activation is thought to deform the plasma membrane using its I-BAR domain and recruit actin polymerization machinery using its other protein–protein interaction domains, thus coordinating two molecular machineries in filopodia (Disanza *et al.*, 2013).

Lamellipodia

Definition

Flat undulating cellular protrusions that appeared to control the direction of cell motility were first observed by Abercrombie and colleagues, when they studied locomotion of cultured fibroblasts. By analogy with filopodia, they named these flat dynamic protrusions ‘lamellipodia,’ and reserved the term ‘lamella’ to refer to a broad flattened sheet of anterior cytoplasm that carries lamellipodia at its tip (Abercrombie *et al.*, 1970).

Behavior and Functions

Lamellipodia are found in virtually all migrating cells and serve as the major cellular engine to propel the leading edge forward. Lamellipodia can generate much greater protrusive forces than filopodia (Cojoc *et al.*, 2007). They also function as navigation devices for guiding a cell around obstacles, sense soluble guidance cues and probe chemical and mechanical properties of the substratum. Although lamellipodia have been mostly studied using cells cultured on a flat solid surface, they are also used for cell migration in 3D environment, but their morphology changes depending on the geometry of available adhesive surface and a balance of intracellular signaling pathways (Petrie and Yamada, 2012).

Lamellipodia typically display cyclic behavior with alternating phases of protrusion and retraction (Abercrombie *et al.*, 1970). The amplitude of these cycles broadly varies among cells. During protrusion phases, the lamellipodia typically lie flat on the substratum, whereas during retraction they often make ruffles, structures formed by the uplifting of flat protrusions. Protrusion–retraction cycles are not tightly coordinated along the leading edge of a cell and show no correlation among leading edge regions separated by more than 5–6 μm .

During migration, lamellipodia need traction to prevent slippage during protrusion. Traction for lamellipodial protrusion is provided by small and dynamic adhesion structures, typically called focal complexes or nascent adhesions (Beningo *et al.*, 2001). These structures mediate linkages between the actin cytoskeleton and the extracellular matrix through transmembrane adhesion receptors that typically belong to the integrin family. Nascent adhesions are formed at the interface between the lamellipodium and the adhesive substrate (Choi *et al.*, 2008) and can subsequently develop into large and stable mature focal adhesions that usually reside behind the lamellipodium in the cell lamella and cell body. Adhesion formation, in general, is a force-dependent process (Burrage and Wittchen, 2013). Formation of nascent adhesions requires fairly small forces, which can derive from myosin II-dependent contraction, actin filament cross-linking (Choi *et al.*, 2008), or a drag applied by the actin retrograde flow (Alexandrova *et al.*, 2008).

Lamellipodia are involved not only in cell migration, but also in formation of cell–cell junctions, such as adherens junctions in epithelial (McNeill *et al.*, 1993) and endothelial cells (Hoelzle and Svitkina, 2012). Flat protrusions homologous to lamellipodia and ruffles also function in phagocytosis (Groves *et al.*, 2008) and micropinocytosis (Kerr and Teasdale,

2009), where they protrude to enclose a solid particle or a portion of extracellular fluid.

Structure

Lamellipodia formed at the leading edge of cells migrating or spreading in 2D culture are best characterized structurally and dynamically. Early electron microscopic studies using thin sections of resin-embedded cells suggested that actin filaments in lamellipodia have distinct organization compared with contractile actin bundles in the same cell (Ludueno and Wesells, 1973). However, preservation of the cytoskeleton was not adequate at that time to define specific details. Subsequently, electron microscopy of negatively stained lamellipodia revealed a network of long diagonal actin filaments oriented with their barbed ends toward the leading edge (Small *et al.*, 1978). Further scrutiny of the actin network architecture by rotary shadowing electron microscopy revealed multiple branched actin filaments in lamellipodia (Svitkina *et al.*, 1997; Svitkina and Borisy, 1999). At branch points, a pointed end of one filament was linked to the side of another filament with the formation of approximately 70° angle between barbed ends of two filaments (Figure 7).

The specific parameters of branched (or dendritic) actin networks in lamellipodia, such as density, length, and orientation of actin filaments or frequency and distribution of branches, vary among cell types and a phase of the protrusion. For example, nascent lamellipodia appear to contain a greater density of branches and shorter individual filaments compared with established lamellipodia undergoing steady state

protrusion (Svitkina and Borisy, 1999; Vinzenz *et al.*, 2012). On the other hand, lamellipodia of neuronal growth cones contain relatively few branches and many long filaments (Korobova and Svitkina, 2008). These parameters of the actin network architecture correlate with the protrusive behavior of the lamellipodium. Thus, lamellipodia containing longer and less branched filaments protrude faster, but are more prone to ruffling and retraction, whereas lamellipodia with shorter and more frequently branched filaments are more persistent, although protrude slower (Bear *et al.*, 2002).

Dendritic actin networks are not restricted to lamellipodia and related membrane protrusions, but also provide pushing force for other cellular activities, such as formation of an endocytic vesicle during receptor-mediated endocytosis (Mooren *et al.*, 2012), or motility and biogenesis of intracellular membrane organelles (Burianek and Soderling, 2013). Certain intracellular pathogens, such as *Listeria monocytogenes* and *Shigella flexneri*, exploit the dendritic nucleation machinery of a host cell to spread from cell to cell while avoiding immune surveillance in the extracellular environment. These and other pathogens use a variety of ways to stimulate assembly of a branched network in the form of elongated 'comet tails,' which propel them through the cytoplasm and into a cellular protrusion, which then can be phagocytosed by another cell (Lambrechts *et al.*, 2008).

Actin Dynamics

Actin dynamics during lamellipodial protrusion displays typical features of treadmilling behavior, as revealed by tracking fiducial marks in the lamellipodial actin network

Figure 7 Actin filament organization in a lamellipodium at the leading edge of a fish epidermal keratocyte. Boxed region is enlarged in the right panel and shows branched actin filaments. Modified from Svitkina, T., 2013. Actin organization. In: Lennarz, W.J., Daniel Lane, M. (Eds.), *Encyclopedia of Biological Chemistry*. Waltham, MA: Academic Press, pp. 27–35.

(Wang, 1985). Thus, actin subunits are added at the leading edge near the plasma membrane, move away from the membrane, and dissipate from the network by the time they reach the lamellipodium base. While polymerizing at the front, the lamellipodial network also undergoes the retrograde flow. As in the case of filopodia, absolute and relative rates of protrusion and retrograde flow vary significantly. The balance between two processes can be controlled in part by the strength of the linkages between the substrate and the lamellipodial actin network (Theriot and Mitchison, 1992).

Despite clear signatures of treadmilling behavior, some parameters of actin dynamics in lamellipodia are not consistent with a simple actin filament treadmilling model, which states that individual actin filaments continuously elongate at their distal barbed ends and depolymerize from their proximal pointed ends. Quantitative analyses of the rate of actin depolymerization in lamellipodia using photoactivated actin marks revealed an extremely fast actin turnover, which was inconsistent with disassembly of a limited number of long filaments from their pointed ends. Also, actin depolymerization occurred evenly throughout the lamellipodium (Theriot and Mitchison, 1991), not only at the base, like in filopodia (Mallavarapu and Mitchison, 1999).

A combination of structural, biochemical, and kinetic data led to a revised model of lamellipodia protrusion, termed the

dendritic nucleation model (Mullins *et al.*, 1998; Figure 8). It posits that the actin filaments in lamellipodia are constantly nucleated as branches on preexisting 'mother' filaments. These 'daughter' filaments elongate and produce force. After a period of elongation, their growth is terminated by capping, while new filaments are nucleated to maintain protrusion. Disassembly of the network occurs through a combination of debranching and severing of actin filaments followed by depolymerization of filament fragments. Thus, the branched network in lamellipodia undergoes treadmilling as a whole by assembling at the front and disassembling throughout its body. In contrast, an individual filament in the network does not treadmill, but is 'born' at a branch point, grows at the barbed end, becomes capped and later 'dies' by depolymerization (Pollard and Borisy, 2003).

The branching network has many advantages for pushing force generation. Newly nucleated filaments are more efficient at pushing, because they are short and stiff. Furthermore, being anchored to the mother filament and through it to the entire lamellipodial network, daughter filaments can immediately do useful work, rather than slip backward in the absence of traction. Repetitive branching allows the network to easily expand or reorient itself by adjusting the rates and sites of nucleation and capping. An angled orientation of pushing actin filaments relative to the membrane is also useful, as it makes it easier to

Figure 8 Schematics of the lamellipodial molecular machinery. The Arp2/3 complex is cooperatively activated by a membrane-targeted nucleation-promoting factor and a pre-existing actin filament. Upon activation, it nucleates a new actin filament at the side of the pre-existing filament and remains associated with the branch point. Branch points are further stabilized by cortactin. The nascent daughter filament elongates with its barbed end oriented toward the membrane. Its elongation is promoted by formins and/or Ena/VASP proteins. After a period of elongation, the barbed end is capped by capping protein and lags behind the advancing leading edge. Disassembly at the rear of the lamellipodial network occurs through dissociation of branches and ADF/cofilin-mediated severing. Modified from Svitkina, T., 2013. Actin organization. In: Lennarz, W.J., Daniel Lane, M. (Eds.), *Encyclopedia of Biological Chemistry*. Waltham, MA: Academic Press, pp. 27–35.

insert an actin monomer between the growing barbed end and the membrane (Mogilner and Oster, 1996).

Molecular Machinery

Assembly of branched networks of actin filaments is controlled by a large number of essential and accessory molecules (Figure 8). Functions of many of these proteins in motility have been revealed by analyzing molecular requirements for *Listeria* motility. A minimal set of key proteins involved in this process have been identified by reconstituting motility of *Listeria* or *Shigella* in a solution of mixed purified proteins (Loisel *et al.*, 1999). A set of essential proteins besides actin itself consisted of the Arp2/3 complex, capping protein, and ADF/cofilin.

The Arp2/3 complex (Machesky *et al.*, 1994; Welch *et al.*, 1997) is a key part of the dendritic nucleation machinery. This heteroheptameric complex nucleates a daughter filament from the side of a mother filament. After nucleation, Arp2/3 complex remains at the branch point, where it links the mother and daughter filaments at the defined angle of 70° and caps the pointed end of the daughter filament to prevent its premature depolymerization (Mullins *et al.*, 1998). Two actin-related proteins within the Arp2/3 complex, Arp2 and Arp3, mimic the barbed end of an actin filament, which allows them to promote nucleation and pointed end capping. Other subunits of the Arp2/3 complex mediate binding to the mother filament. The Arp2/3 complex is intrinsically inactive and has Arp2 and Arp3 separated from each other. To acquire nucleating capability, the Arp2/3 complex needs to be activated by a nucleation-promoting factor that acts in cooperation with the mother filament (Machesky *et al.*, 1999). Following activation, Arp2 and Arp3 within the complex acquire a mutual arrangement mimicking the barbed end. Most important nucleation-promoting factor belong to WASP family (Burianek and Soderling, 2013; Campellone and Welch, 2010). In lamellipodia, Arp2/3 complex is predominantly activated by WAVE proteins, which exist in the form of a pentameric complex (Eden *et al.*, 2002). Other nucleation-promoting factors function at distinct subcellular locations, such as various membrane organelles (Campellone and Welch, 2010).

Heterodimeric capping protein consisting of α and β subunits tightly binds barbed ends of actin filaments preventing their polymerization and depolymerization. Such capping activity is necessary to terminate excessive barbed ends constantly generated by the Arp2/3 complex and thus maintain the steady state actin dynamics in the branched network (Mejillano *et al.*, 2004). Capping protein is the predominant barbed end capper in lamellipodia (Schafer *et al.*, 1998), but the other barbed end capping proteins, such as Eps8, gelsolin, and Aip1, are also present in lamellipodia and may contribute to the dynamics of branched networks (Zigmond, 2004).

Under steady state conditions, actin polymerization should be balanced by depolymerization. Disassembly of branched actin networks is primarily carried out by ADF/cofilin proteins (Bamburg *et al.*, 1980; Bernstein and Bamburg, 2010), which sever actin filaments throughout the lamellipodium, except for the very front, where actin filaments are enriched in ATP-loaded subunits and therefore poorly bind ADF/cofilin (Svitkina and Borisy, 1999). ADF/cofilin typically functions together

with Aip1, which activates cofilin's severing activity and also caps the newly formed barbed end to prevent its growth or annealing (Okada *et al.*, 1999). However, in some cases, ADF/cofilin appears to sever actin filaments without capping, so that newly formed barbed ends promote polymerization, rather than depolymerization (Zebda *et al.*, 2000). Srv2/CAP proteins also enhance ADF/cofilin-mediated severing (Chaudhry *et al.*, 2013). ADF/cofilin can also debranch daughter filaments by changing conformation of the mother filament (Blanchoin *et al.*, 2000). Debranching can also be induced by cofilin-related GMF proteins (Gandhi *et al.*, 2010) and by coronins (Cai *et al.*, 2008); these proteins act through binding to the Arp2/3 complex.

Many other proteins improve the performance of the dendritic nucleation machinery in the cell. Actin elongation is assisted by profilin (Syriani *et al.*, 2008), formins (Yang *et al.*, 2007) and Ena/VASP proteins (Bear *et al.*, 2002). Actin-binding protein cortactin promotes binding of the Arp2/3 complex to actin filaments and thus stabilizes branches (Weaver *et al.*, 2001). Cross-linkers filamin A (Flanagan *et al.*, 2001) and α -actinin (Hamill *et al.*, 2013) likely consolidate the whole network. Numerous upstream regulators modulate functions of various components of the lamellipodial molecular machinery and thus control behavior of lamellipodia. For example, high activity of actin filament elongation factors, such as Ena/VASP (Bear *et al.*, 2002) and formin (Yang *et al.*, 2007), produces numerous long actin filaments within the branched actin network, which can be bundled with the formation of filopodia (Svitkina *et al.*, 2003), or buckled under the influence of membrane tension and produce ruffles (Bear *et al.*, 2002).

The Extracellular Matrix

Extracellular Matrix

Multicellular organisms require extracellular matrix (ECM) for viability and some form of ECM is even produced by single cell bacteria. The ECM of mammals can be divided into two broad categories: basement membranes/basal lamina and connective tissue. Whereas basement membranes are characterized by a thin, planar structure, connective tissue or interstitium is characterized as a space-filling type of ECM rich in fibrillar collagens, proteoglycans, and glycosaminoglycans (Figure 1). These two types of ECM will be discussed in general terms here and the reader should be informed that each organ (and in most cases, specific structures within each organ) contains tissue-specific ECM elements both in terms of basement membranes and connective tissue. As an example, shown in Figure 2 is a schematic representation of a large blood vessel that contains basement membrane, elastic lamellae, and connective tissue. For the sake of brevity with respect to references, in many cases pertinent reviews of each topic are provided so that the reader is encouraged to seek out for further detail and for direction to original references with experimental detail.

Basement Membranes

Early in development, during the peri-implantation period, deposition of the first basement membrane components are produced by the primitive endoderm of the inner cell mass

and assembled on trophoectodermal surfaces (Miner and Yurchenco, 2004). The formation of this first basement membrane is necessary for survival and further development of the embryo illustrating the critical role of this ECM in mammalian life. In fact, proteins of the basement membrane are represented in all forms of multicellular life where they serve vital functions in maintaining and instructing cellular processes. Thus the study of basement membrane proteins in model organisms such as *Drosophila melanogaster* and *Caenorhabditis elegans* has provided valuable insight into structure and function of this ECM (Kelley et al., 2014; Pastor-Pareja and Xu, 2011).

Developmental processes that rely on basement membrane assembly include, cell survival, migration, differentiation, and organization of tissues and organs. In the adult, polarized cell types such as epithelial and endothelial cells have a basement membrane associated with the basal side of each cell. In contrast, muscle cells, Schwann cells, and adipocytes are surrounded by a basement membrane on all sides. The basement membrane serves to provide structural support to cells that is needed for maintaining mechanical stability of tissues. However, the basement membrane also serves many other important functions including control of cell polarization, macromolecular diffusion/filtration, sequestration of cytokine and growth factors, and regulation of both immune and oncogenic cell intravasation/extravasation. Basement membranes serve to delineate cell compartments and also to facilitate linking of epithelial and endothelial layers to underlying connective tissues.

Figure 1 The left panel shows a schematic depiction of an epithelial cell layer with an underlying basement membrane that separates the cells from the connective tissue. Represented structures in the connective tissue are collagen fibers (blue), microfibrils (green), and elastic fibers (purple). Proteoglycans that bind to ECM components are shown by pink rectangles. Fibroblasts, cells that do not have an associated basement membrane, populate the connective tissue. The right panel is a transmission electron microscopy image of the dermal-epidermal border of murine skin. Note the bilayer structure of the basement membrane comprised of the basal lamina and the reticular lamina visible in this image. Collagen fibers in the dermal connective tissue are evident beneath the basement membrane.

Figure 2 Schematic representation of a large blood vessel. The endothelial cells, the associated underlying basement membrane, and the internal elastic membrane comprise the intima (red lettering). The smooth muscle cells and external elastic membrane comprise the media (blue lettering). The outer layer is the adventitia (green lettering), a connective tissue rich in fibrillar collagens.

Of note, the terms basal lamina and basement membrane have been used somewhat interchangeably. Historically, basement membranes were defined as bilayer structures as viewed under the electron microscope composed of a basal lamina - an internal felt-like structure - and an external reticular lamina (see [Figure 1](#); [Sanes, 2003](#)). Hence, the term basement membrane was to include the basal lamina but also the external reticular lamina. However, recent data suggest that the bilayer appearance of basement membranes arises as an artifact of fixation and that, *in vivo*, these structures resemble a homogenous single layer ([Chan and Inoue, 1994](#); [Miosge, 2001](#)). Each basement membrane contains four basic components: laminin, collagen IV, nidogen, and heparan sulfate proteoglycans, perlecan and agrin ([Figure 3](#)), although many basement membranes in specific tissues have a more complex protein composition that includes additional components ([Yurchenco, 2011](#)).

Laminins

Laminin is a structural protein that forms a network-like structure. The three subunits of laminin - α , β , and γ - are translated into the endoplasmic reticulum where the subunits assemble to form a trimeric protein which then undergo glycosylation. The post-translational glycosylation modifications on laminin are further processed in the Golgi Apparatus prior to secretion into the extracellular space ([Hohenester and Yurchenco, 2013](#)). The laminin network undergoes self-assembly in close association with the cell surface. Each laminin protein forms either a cross-like structure, a Y-shaped structure, or a rod-shaped structure dependent upon the subunit composition that consists of one α , one β , and one γ subunit ([Suh and Miner, 2013](#)). Interaction of laminin with cell surface receptors serves to increase the effective concentration of laminin to facilitate assembly into networks ([Hohenester and Yurchenco, 2013](#)). Assembly of the laminin network

requires Ca^{2+} and is a reversible process in contrast to collagen IV networks, for example, that are stabilized by covalent cross-linking (see below). Laminins serve as a primary cell-binding ligand via cell surface receptors such as integrins and α -dystroglycan. Cytoplasmic domains of integrins and α -dystroglycan receptors form complexes with intracellular scaffolding proteins that interact with cytoskeletal elements. Thus, engagement of laminin by these cell surface receptors serves to link basement membrane ECM with the cytoskeleton to facilitate, for example, cell adhesion and cell movement ([Yurchenco, 2011](#)).

Although the laminin nomenclature has undergone several iterations, the current presiding nomenclature defines each laminin family member from its respective subunit composition. For example, laminin 111 is composed of $\alpha 1$, $\beta 1$, $\gamma 1$ subunits whereas laminin 511 is composed of $\alpha 5$, $\beta 1$, and $\gamma 1$ subunits ([Aumailley et al., 2005](#)). Laminin trimers are formed by the nonrandom assembly of one of each of the five α , four β , and three γ chains to produce at least 15 known different heterotrimers ([Aumailley et al., 2005](#)). The molecular weight of laminin 111 is ~ 900 kD.

Self-assembly of the laminin network occurs at the cell surface and is mediated by interaction of the three 'short arms' of the laminin cross-shaped molecule ([Hohenester and Yurchenco, 2013](#)). Notably, laminins that lack short arms, such as 411 and 421, are not able to independently polymerize to form a network, although can be incorporated into basement membranes via interaction with other forms of laminin. The 'long arm' of the laminin cross contains the LG domains that are the primary sites for laminin receptor binding including laminin-binding integrins and α -dystroglycan ([Yurchenco, 2011](#)). In addition, the proteoglycan agrin binds $\gamma 1$ at a site in the long arm of the molecule with high affinity, which provides additional linkages of laminin networks to cell surfaces ([Suh and Miner, 2013](#)).

Polymerization of the laminin network at the cell surface is required for basement membrane assembly. Abrogation of

Figure 3 A representation of the current model of interaction of the four principle components of basement membranes in association with cell surfaces. The laminin network forms adjacent to the cell surface and engages cell surface receptors. The collagen IV network forms more distal from the cell surface. Heparan sulfate proteoglycans, for example, perlecan, link the laminin network to the collagen IV network, whereas nidogen interacts with each network independently (see text for specific references).

laminin expression leads to a complete absence of basement membranes in the embryo (Smyth *et al.*, 1999). In contrast, deletion of collagen IV, the other primary basement membrane protein network, does not lead to an absence of a laminin network and basement membranes form to some extent in collagen IV null mice (Poschl *et al.*, 2004). However, basement membranes produced in the absence of collagen IV eventually fail presumably due to an inability to maintain structural integrity that results in embryonic lethality (Poschl *et al.*, 2004).

Collagen IV

Collagen IV is the most abundant protein in basement membranes and also forms a polymerized network, similar to that of laminin (Khoshnoodi *et al.*, 2008). Collagen IV networks are assembled adjacent to, but independent of, the laminin network. In fact, laminin networks can be biochemically separated from collagen IV networks to reveal two distinct polymeric structures (Behrens *et al.*, 2012). Whereas laminin assembles in association with the cell surface, collagen IV networks are elaborated at a more distal location from the cell surface. In some cases, such as the dermal–epidermal junction and skeletal muscle, collagen IV has been shown to be produced by cells in the interstitial ECM and thus these cells are also thought to contribute to basement membrane construction (Kuhl *et al.*, 1984).

Like all members of the collagen family, collagen IV is a trimeric protein made up of three α subunits (Prockop and

Kivirikko, 1995). Collagen IV has a molecular weight of ~ 160 kD. Collagen IV proteins are encoded by six separate α chains that assemble to produce distinct collagen IV family members (Khoshnoodi *et al.*, 2008). The most abundant form of collagen IV is comprised of two collagen $\alpha 1(\text{IV})$ chains and one $\alpha 2(\text{IV})$ chain $[(\alpha 1(\text{IV}))_2 \alpha 2(\text{IV}); \alpha 112]$. The other two known forms of collagen IV have the composition $[(\alpha 3(\text{IV}) \alpha 4(\text{IV}) \alpha 5(\text{IV}); \alpha 345)]$ and $[(\alpha 5(\text{IV}))_2 \alpha 6(\text{IV}); \alpha 556]$. These different forms of collagen IV can assemble into either homotypic or heterotypic polymers or networks as described below (Cummings and Hudson, 2014).

Characteristically, collagen IV proteins have spans of Gly-X-Y repeats indicative of all collagen family members where glycines (Gly) are often followed by proline (X) and hydroxyproline (Y). However, in contrast to fibrillar collagens, the triple helical coiled coil segments formed from the repeated Gly-X-Y sequences (the collagenous domain) in collagen IV are interrupted such that the overall tertiary structure of collagen IV is more flexible than the rod-like fibrillar collagens (Prockop and Kivirikko, 1995). The C-termini of each α subunit, termed the non-collagenous (NC) 1 domain, designates chain recognition in the endoplasmic reticulum to initiate trimerization of the appropriate α subunits to form the three protomers of collagen IV: $\alpha 112$, $\alpha 345$, or $\alpha 556$. Once secreted into the extracellular space, a sulfilimine cross-link in the NC1 domains of one protomer forms a covalent bond with another protomer of collagen IV to initiate network assembly (Cummings and Hudson, 2014). The enzyme peroxidase catalyzes the formation of this sulfilimine bond and requires ionic bromide

(Br-) (McCall *et al.*, 2014). The N-terminal region of collagen IV is referred to as the 7S domain based on its sedimentation coefficient. The 7S domain mediates intermolecular association of four collagen IV molecules and is also a site of intermolecular cross-linking of the collagen IV network. Cross-linking of collagen IV molecules at the N and C termini stabilize the network which is further reinforced through lateral intermolecular associations of the collagenous domains (Khoshnoodi *et al.*, 2008).

The composition of the networks and the relative amounts of collagen IV has significant influence on functional parameters of basement membranes such as permeability, charge-selectivity, tensile strength, and cell interaction. For example, the $\alpha 345$ network is more interconnected and more highly cross-linked in comparison to the network generated from $\alpha 112$ and is therefore likely to provide increased tensile strength to the basement membrane (Gunwar *et al.*, 1998). In kidney development, for example, the glomerular basement membrane is composed primarily of $\alpha 112$ at early stages but is replaced by $\alpha 345$ in the mature glomerulus presumably to provide increased structural support as blood pressure through the glomerulus increases with age (Suh and Miner, 2013). Mutations in genes encoding $\alpha 345$ have been found in patients with kidney disease, including Alport's syndrome, demonstrating the functional importance of collagen IV in the glomerular basement membrane. Likewise mutations in genes encoding the $\alpha 1$ and $\alpha 2$ subunits (COL4A1 and COL4A2) lead to perinatal cerebral hemorrhage and porencephaly, for example (Suh and Miner, 2013; Gould *et al.*, 2005). Hence, the distribution of different polymers of collagen IV is both tissue-specific and dictated by functional requirements of specific basement membranes within a given tissue.

Nidogens

The proteoglycan nidogen (also known as entactin) is also a ubiquitous component of basement membranes with a molecular weight of ~ 150 kD (Yurchenco, 2011). There are two nidogen family members, Nidogen 1 and Nidogen 2. Expression of mRNA encoding nidogens is predominantly associated with cells of mesenchymal origin whereas nidogen proteins are found within basement membranes (Breitkreutz *et al.*, 2013). Therefore nidogens provide another example of the mesenchymal contribution to basement membranes that form adjacent to epithelial cells. Expression patterns and protein localization patterns of nidogen 1 and 2 are overlapping (Breitkreutz *et al.*, 2013). Transgenic mice that lack either nidogen 1 or lack nidogen 2 expression displayed mild phenotypes with no apparent alterations in basement membranes, presumably due to compensation from continued expression of the alternate nidogen. However, mice with abrogated expression of both nidogen 1 and 2 display perinatal lethality with defects in lung and heart basement membranes (Bose *et al.*, 2006). Interestingly, other basement membranes in the double nidogen null mice exhibited apparently normal morphology including the dermal-epidermal junction of the skin. Thus, different basement membranes in the body appear to have different dependencies upon the presence of nidogen for their integrity.

In vitro, nidogen binds to both collagen IV and laminin with fairly high affinity and has been proposed to serve as a molecular bridge or linking molecule that tethers the laminin and collagen IV networks together and thus stabilizes basement membranes. However, recent studies have challenged the strength of the molecular cross-bridge formed by nidogen. In studies by Behrens *et al.* (2012) linking of the laminin and collagen IV networks was dependent upon the heparan sulfate proteoglycan perlecan whereas nidogens were found to associate within both laminin and collagen IV networks but not as a cross-bridge between the two. Nidogens also function to sequester and distribute growth factors in the basement membrane. For example, the growth factor FGF-8 demonstrated altered localization in nidogen double null animals and this was associated with syndactyly and aberrant limb development in these mice (Bose *et al.*, 2006).

Heparan Sulfate Proteoglycans

Heparan sulfate proteoglycans are integral components of basement membranes. Like nidogen, heparan sulfate proteoglycans perlecan and agrin contain both laminin and collagen IV binding sites (Iozzo, 2005; Bezakova and Ruegg, 2003). As mentioned above, current evidence supports a stronger function of perlecan in tethering the two networks together than that of nidogen (Behrens *et al.*, 2012). Agrin is also known to provide additional indirect linkage of laminin trimers to the cell surface. Agrin was originally identified as a critical component of the basement membrane at the neuromuscular junction. Non-muscle agrin is now appreciated as having a broad expression profile in basement membranes throughout the body (Bezakova and Ruegg, 2003). Perlecan expression is not limited to basement membranes and is also found in cartilage and in some connective tissues (Iozzo, 2005).

Heparan sulfate proteoglycans bind to a number of cytokines and growth factors including fibroblast growth factors, platelet derived growth factor, vascular endothelial growth factor among many others (Iozzo, 2005). Hence these proteoglycans can sequester molecules in the ECM. These molecules can serve to establish gradients, inhibit activity, or increase activity of these factors by presenting them to cell surface receptors thereby enhancing receptor binding.

Other ECM Proteins Associated with Basement Membranes

In addition to the four primary constituents of the basement membrane outlined above, other proteins associated with this ECM include collagen XV and XVIII, also heparan sulfate proteoglycans, and collagen VI (Iozzo, 2005; Fitzgerald *et al.*, 2013). These collagen family members are thought to function at the interface between the outer basement membrane and the underlying connective tissue and serve to link the basement membrane to the stroma. In the case of the dermal-epidermal junction, collagen VII is another important linker molecule that attaches the epidermal basement membrane to the dermal interstitium through looping structures

(Nystrom *et al.*, 2013). Blistering disorders of the skin are associated with mutations in collagen VII due to weakening of these collagen VII anchoring fibrils (Nystrom *et al.*, 2013).

The proteins represented in this overview of basement membranes represent the basic components present in the greatest quantity. In fact, the number of ECM proteins associated with basement membranes is rapidly expanding. A recent proteomic analysis using human glomerulus revealed 144 extracellular proteins that were identified in glomerular extracts (Lennon *et al.*, 2014). Likely, other basement membranes isolated from other tissue sources will reveal similar complexity albeit with differences in the profile of extracellular proteins. The field of basement membrane biology is rapidly expanding as the importance of this fundamental aspect of multicellular life, with great significance to development, health, and disease progression, becomes increasingly more appreciated.

Fibronectin

Fibronectin is a critically important ECM protein that mediates cell:ECM interaction during fundamental events such as development, wound healing, fibrosis, and tumor progression (Schwarzbauer and DeSimone, 2011). Fibronectin is secreted as a soluble, covalently bound dimer of ~440 kD molecular weight. Fibronectin is encoded by a single gene however different forms of fibronectin arise through alternative splicing. Circulating fibronectin is produced primarily in the liver and this soluble form of fibronectin is referred to as plasma fibronectin. Cellular fibronectin is produced in a variety of different tissues by resident cells including connective tissues, bone, and periodontal tissues. Antibodies have been generated that distinguish between plasma and cellular fibronectin based on sequence specific epitopes that represent individual forms of fibronectin. The splice variants of fibronectin have been shown to exhibit differential solubility and sensitivity to protease digestion suggesting that expression of each fibronectin variant can influence fibronectin network formation and stability (White and Muro, 2011).

Like laminin, fibronectin assembles into a network on cell surfaces. However, in contrast to laminin where increasing effective concentrations in the pericellular space drives polymerization, in the current model of fibronectin assembly, force generated by the actin cytoskeleton relayed through cell surface integrin receptors drives fibronectin fibrillogenesis (Schwarzbauer and DeSimone, 2011). Fibronectin-binding integrins link to the cytoskeleton through scaffolding proteins that allow forces generated by the actin/myosin cytoskeletal elements to pull on fibronectin to expose an assembly site that is not available in the folded, soluble conformation. The tension generated by the actin cytoskeleton transferred through integrin engagement reveals the site that initiates fibronectin polymerization. The force generated through the actin cytoskeleton is required for fibronectin fibrillogenesis. Syndecans, transmembrane proteoglycans, enhance fibronectin-integrin engagement on cell surfaces and also influence fibronectin assembly (Schwarzbauer and DeSimone, 2011).

Once fibronectin fibrillogenesis is initiated a series of steps that are not completely understood convert the polymerized fibronectin into an insoluble ECM. Formation of insoluble

fibronectin likely involves protein:protein interactions and additional conformational changes that result in a stabilized ECM (Schwarzbauer and DeSimone, 2011). Notably, experiments that have contributed to our current model of fibronectin network formation were predominantly carried out in 2-dimensional cell culture systems. The process that occurs in developing and adult tissues is likely to be more complex and depend upon additional factors such as intrinsic levels of tissue-specific tension, for example. The cortical actin cytoskeleton and regulation by Wnt/PCP (planar cell polarity) pathways *in vivo* have also been implicated in fibronectin assembly in zebra fish models (Dohn *et al.*, 2013).

Formation of a stable fibronectin network is thought to precede and further enhance assembly of other ECM components including collagen fibrils and microfibril networks - a precursor of elastic fiber formation. Hence, fibronectin has been described as a 'master regulator' of ECM assembly. Accordingly, fibronectin has been shown to interact with a variety of ECM proteins including, fibrin, thrombospondin, transglutaminase, and collagens (Halper and Kjaer, 2014).

As mentioned previously, fibronectin plays critical roles in many important cellular processes both in development and adult tissues. Notably, fibronectin is required in the early embryo for mesodermal migration demonstrated in mice, chick, and zebra fish. Polymerization of fibronectin has also been shown to drive branching morphogenesis of developing glands in organ culture models (Larsen *et al.*, 2006). In adult tissues, fibronectin is an important component of blood clots, a critical factor in cell migration during wound healing events, and an important factor in bone maintenance and repair - to name just a few events that depend upon fibronectin expression and deposition.

Connective Tissue/Interstitium

In contrast to basement membranes that form a thin, planar structure, connective tissue ECMs are a space-filling type of matrix. Connective tissue is abundant in fibrillar collagens, proteoglycans and glycosaminoglycans and provides critical structural support in vertebrates (Prockop and Kivirikko, 1995). Mineralized tissues such as bone and teeth are also examples of tissues rich in fibrillar collagens and associated proteoglycans. Similar to basement membranes, the profile of ECM proteins in a given connective tissue is governed by functional requirements of the particular tissue and can vary widely throughout an organism. Skin, tendon, cornea, blood vessel walls, and ligaments are all examples of connective tissue and each has a tissue-specific pattern of ECM components that gives rise to each unique and specialized organ (Figure 4). Notably, the primary component of each of these tissues is collagen I, the prototypic fibrillar collagen, that serves as a remarkably versatile 'building block.' Manipulation and assembly of the same collagen I protein and associated tissue-specific ECM partners by resident cells gives rise to a transparent tissue in cornea and to the strength bearing fibers of tendon. The orientation and the diameter of collagen fibers assembled are two examples of critical parameters that influence tissue architecture and ultimately connective tissue function.

Figure 4 Transmission electron microscope images of the collagenous ECM of tendon and dermis. Individual collagen fibrils are visible by EM. Bundles of collagen fibrils make up collagen fibers. Note the differences in collagen fibril orientation between tendon (parallel alignment) and dermis (various orientations). The 67 nm *D*-periodicity of collagen fibrils are visible in dermal fibrils that run parallel to the plane of section.

Fibrillar Collagens

Collagens I, II, III, and V are structurally very similar (Kadler *et al.*, 2007). These fibril-forming collagen family members are triple helical, like all collagens, and have a long rod-like structure generated by a relatively long, uninterrupted span of Gly-X-Y amino acids (see Section Collagen IV). The three α chains of each are held together through interchain hydrogen bonds. Whereas collagen I is a heterotrimer composed of two $\alpha 1(I)$ and one $\alpha 2(I)$ chains, most fibril-forming collagens are homotrimers composed of a single type of α chain, for example, $\alpha 1(II)_3$ and $\alpha 1(III)_3$ for type II and type III collagen, respectively (Prockop and Hulmes, 1994). Collagen I has an approximate molecular weight of 300 kD. However due to the characteristic rod-like shape of fibrillar collagens, the migration of these proteins on, for example, sodium dodecyl sulfate polyacrylamide electrophoresis (SDS-PAGE) gels, is not relative to standard globular proteins.

Indicative of most secreted proteins, the α subunits of collagens are translated into the endoplasmic reticulum where the triple helices are assembled. A number of chaperones in the endoplasmic reticulum and Golgi Apparatus facilitate collagen subunit assembly and modifications including glycosylation and hydroxylation of prolines and lysines. Chaperones for collagen include heat shock protein 47, protein disulfide isomerase, hydroxylases, and glycosyltransferases (Myllyharju and Kivirikko, 2004). Chain recognition sequences in the C-terminal propeptide domain of each subunit allow for triple helical assembly of appropriate α subunits so that α subunits of collagen I do not form trimers with those of type III, for example. Initiation of triple helical folding occurs at the C-terminus and proceeds toward the N-terminus of the protein. Secretion of the rod-shaped procollagen molecules require specialized machinery as typical transport vesicles used for globular proteins cannot accommodate fibrillar procollagens (Canty and Kadler, 2005).

Procollagen molecules are soluble precursors that are processed to fibril-forming collagen monomers. The C-propeptide is removed by bone morphogenic protein-1/tolloid proteinases whereas the N-terminal propeptide is released by enzymes in the A Disintegrin and Metalloproteinase (ADAM-TS)

family. Enzymatic clipping of the prodomains of collagen convert soluble procollagen to collagen monomers that can be incorporated into insoluble ECM (Canty and Kadler, 2005). Therefore, regulatory factors that influence cleavage of propeptides of fibrillar collagens influence collagen deposition into fibrillar, insoluble ECM. In embryonic tendon, specialized cellular structures termed fibropositors have been described as sites of procollagen processing and nascent fibril assembly sites. These structures are characterized by extended pockets that associate both with intracellular vesicles and extend into the extracellular space (Canty *et al.*, 2004). These structures are abundant in embryonic tissues undergoing high rates of collagen fibril production but have also been observed in some adult tissues that undergo high rates of collagen turnover, such as the periodontal ligament. The exact mechanisms by which cells secrete collagen and influence collagen assembly, particularly in regards to the generation of tissue-specific architectures, continue to be an active area of research.

Collagen monomers are assembled into collagen fibrils in an ordered, staggered array that gives rise to fibrils with a characteristic 67-nm *D*-periodic repeat structure (Orgel *et al.*, 2011). Collagen fibrils undergo further aggregation in the extracellular space to form collagen fibers. Collagen fibrils are visible by electron microscopy and can range from ~ 12 to ~ 500 nm. Bundles of collagen fibrils make up collagen fibers that are visible by light microscopy (Figure 4). Insight into the macromolecular organization of collagen fibers is progressing although many aspects of fiber architecture remain to be determined (Orgel *et al.*, 2011). Importantly, collagen fibrils are not composed of single collagen types but are composite in nature. Evidence that collagen V initiates formation of collagen I containing fibrils, for example, was found in the analysis of collagen V null mice. Collagen fibrils containing types I and III are found in many connective tissues including: skin, tendon, bone, and ligament. Type II collagen fibers are found predominantly in cartilages, vitreous, and intervertebral disc and can also include type III collagen, as another example (Wu *et al.*, 2010).

Insoluble collagenous ECM is generated through the formation of inter and intramolecular covalent cross-links (Eyre *et al.*, 1984). Lysyl oxidase mediated collagen cross-links are the best characterized but other types of cross-links include

those mediated by transglutaminase and nonenzymatic advanced glycation end-products (Wang *et al.*, 2014; Goh and Cooper, 2008). Lysyl oxidase functions in the extracellular space to modify specific amino acids in the telopeptide domain of fibrillar collagens. Upon incorporation of lysyl oxidase-modified monomers into collagen fibrils, covalent cross-link formation occurs. Differences in collagen cross-linking can influence collagen solubility, fibril diameter, sensitivity to degradation, ECM composition, tensile strength, stiffness, and matrix permeability (Eyre *et al.*, 1984).

Collagen fibers can be organized into a number of different types of tissues. The orthogonal array of collagen fibers in cornea with fairly uniform diameters, gives rise to a transparent tissue. Collagen fibers in the skin are tightly arranged in various orientations with a range of fibril and fiber diameters that provide tensile strength in different directions as well as providing a barrier function for the dermis (Figure 4). Collagen fibers in tendons tend to be large bundles of collagen fibrils that align in one direction to transmit forces from skeletal muscles to bones (Figure 4). A number of different types of molecules can contribute to tissue-specific collagen organization.

FACIT Collagens and SLRPs

Fibril-associated Collagens with Interrupted Triple Helices (FACIT) collagens include collagens types IX, XII, XIV, XVI, XIX, XX, XXI, and XXII (Ricard-Blum, 2011). FACIT collagens are frequently found associated with the surface of collagen fibrils and are considered important mediators of collagen fiber organization (Kadler *et al.*, 2007). Small leucine rich proteoglycans (SLRPs) also contribute to collagen fibril and fiber architecture. Decorin, for example, was so named for its capacity to 'decorate' collagen fibers. Mice that do not express decorin exhibit differences in collagen fibril diameter that become more phenotypically distinct with the compound loss of another SLRP, biglycan (Chen and Birk, 2013). Other SLRPs implicated in collagen fiber morphology include: lumican, asporin, fibromodulin, and osteoglycin (for a complete list and review see reference Chen and Birk (2013)).

In addition to the role of proteoglycans in collagen fiber organization, these molecules are also hydrophilic and increase the water content of connective tissues. Glycosaminoglycans such as hyaluronic acid (HA) also facilitate water retention and play key roles in cell migration and ECM deposition (Wang *et al.*, 2011). Connective tissue ECMs can serve as reservoirs for secreted factors such as growth factors, cytokines, and inactive forms of digestive enzymes. Proteoglycans are considered a primary component facilitating the sequestration of signaling molecules in the ECM.

Elastic Fibers

Elastic fibers, the largest ECM structures, provide elasticity to tissues. This property is especially critical for organs such as lung and large blood vessels to allow for elastic recoil of these tissues (Figure 2). Elastic fibers are composed of two components, one made up primarily of elastin protein and the second being a complex of proteins, rich in fibrillins, that form

microfibrils (Wagenseil and Mecham, 2007). Elastin is encoded by a single gene in humans that, like fibronectin, gives rise to different protein forms as a result of tissue-specific alternative splicing of the mRNA. In the current model of elastic fiber assembly, elastin is secreted as tropoelastin and coacervates or aggregates through self-assembly to form an amorphous, hydrophobic core that is cross-linked by lysyl oxidase, the enzyme that also cross-links fibrillar collagens. Formation of elastin aggregates occurs at assembly sites on the cell surface and is facilitated by cell surface components such as heparan sulfate proteoglycans. The aggregates are then transferred to microfibrils. Component of microfibrils include fibrillins, fibulins, EMILIN-1, and microfibril associated glycoproteins (MAGPs) (Wagenseil and Mecham, 2007). Microfibrils are also present in tissues independent of elastic fibers and function as structural elements as well as in the sequestration of growth factors such as transforming growth factor (TGF) β . Examples of diseases associated with mutations in genes encoding fibrillin are Marfan's syndrome and congenital contractural arachnodactyly (Ramirez and Dietz, 2004). Mutations in elastin can give rise to the condition cutis laxa, a disorder characterized by sagging, inelastic skin among other symptoms (Halper and Kjaer, 2014).

Matricellular Proteins

Matricellular proteins were originally defined as proteins that associate with the ECM but do not contribute structural elements and were therefore distinguished from classical ECM components such as laminins and collagens (Bornstein, 1995). Primarily, matricellular proteins are viewed as molecules that mediate cell:ECM interaction (Murphy-Ullrich and Sage, 2014). Many matricellular proteins bind to cell surface receptors and to structural components of the ECM and thus influence a broad range of cellular events. Importantly, expression and activity of matricellular proteins in general tends to be highly contextual and can vary significantly depending on the cellular milieu. The matricellular family includes, SPARC and SPARC-like proteins, thrombospondins, tenascins, osteopontin, periostin, fibulins, and Cyr, CTGF, Nov (CCN) proteins.

SPARC is a prototypic matricellular protein characterized by a modular domain structure. In the absence of SPARC expression, differences in connective tissue ECM are detected that generally become more advanced with age (Bradshaw, 2009). Shown in the top panel of Figure 5 is a SPARC-null mouse that appears to have a grossly normal phenotype with the exception of a curled tail. At the level of the electron microscope, differences in collagen fibril organization are apparent in the tail tendon of these mice (Figure 5, lower panels). Similar to the phenotype of other mice with abrogated expression of specific matricellular proteins, SPARC-null mice have subtle phenotypic differences until challenged (Bradshaw, 2012; Murphy-Ullrich and Sage, 2014). However, SPARC-null mice, for example, are unable to mount a significant fibrotic response after injury in many tissues including liver, kidney, lung, heart, and skin (Bradshaw, 2009).

In most cases, matricellular proteins are expressed more highly in developing tissues and have reduced expression in adult tissues. In response to different types of injury or tumor

Figure 5 Top panel: SPARC-null mice exhibit curled tails. Bottom panel: Images of tail tendon from normal (wild-type) mice and SPARC-null mice at 1 month of age taken by transmission electron microscopy. Note the differences in collagen fiber organization in the absence of SPARC expression (highlighted in red).

development, re-expression of robust amounts of particular matricellular proteins are frequently observed. For example, significant increases in matricellular protein expression are often found in tissues undergoing wound healing, tumor progression, and fibrosis. The expression patterns and the general phenotype of the null mice suggest that matricellular proteins are important mediators of cell activity in response to injury and ECM remodeling. These proteins are recognized as critical regulators of a wide variety of cellular activities including: ECM assembly, inflammation, fibrosis, wound healing, migration/metastasis, growth factor activity, synapse formation, calcification, and apoptosis (Murphy-Ullrich and Sage, 2014).

Conclusions

- ECMs are required for multicellular life.
- Tissue-specific ECMs dictate form and function in tissues and organs.
- There are two primary types of ECM: basement membrane/basal lamina and connective tissue.
- There are four primary components of basement membranes: laminins, collagen IV, nidogens, and heparan sulfate proteoglycans.
- Laminin and collagen IV form independent networks and each type has the capacity to self-assemble.
- Collagen IV networks are stabilized by covalent cross-links whereas laminin network assembly is reversible.
- Nidogen and heparan sulfate proteoglycans confer stability to basement membranes as well as serving to sequester growth factors and to interact with cell surface receptors.
- Fibronectin is a critical ECM protein essential for development and serves as a 'master regulator' of many structural elements in the ECM.
- Connective tissue ECM is primarily composed of fibrillar collagens, proteoglycans, and glycosaminoglycans.
- Fibrillar collagens are synthesized as soluble procollagen molecules.

- Removal of the propeptides of fibrillar collagen precedes insoluble incorporation of collagen monomers to collagen fibrils.
- Collagen fibrils and fibers are composites of multiple types of collagens and associated proteoglycans such as those of the SLRP family.
- Collagen fibrils and fibers are stabilized by the formation of intra and intermolecular cross-links.
- Elastic fibers include an elastin component assembled onto microfibrils. Protein components of microfibrils include fibrillins, fibulins, EMILIN-1, and MAGP.
- Matricellular proteins mediate cellular interaction with structural ECM components and are essential factors in a variety of tissue processes

Cell–Cell Adhesion and the Cytoskeleton

BR Acharya and AS Yap, The University of Queensland, Brisbane, QLD, Australia

© 2016 Elsevier Inc. All rights reserved.

Introduction

Cell–cell adhesion helps shape tissue organization during morphogenesis and preserves tissue cohesion in post-developmental life. In doing so, cell adhesion molecules influence diverse cellular processes, including cell–cell cohesion, recognition, signaling, and the regulation of cell proliferation. A variety of types of cell–cell adhesion molecules are now known, such as cadherins, nectins, and adhesion molecules of the immunoglobulin (Ig) superfamily. In this article, we focus on how cytoskeletal systems interact with cell adhesion receptors to influence their biological functions. Cell–cell adhesion is commonly supported by transmembrane adhesion receptors whose cytoplasmic tails can associate physically with cytoskeletal elements and, often, also regulate the dynamics and organization of those cytoskeletal partners. Indeed, all of the three major cytoskeletal components of eukaryotic cells – actin microfilaments (MFs), intermediate filaments (IFs), and microtubules (MTs) – can interact with cell–cell adhesion receptors. Here we will outline how these interactions occur and their functional implications. Increasingly, it is apparent that cell–cell adhesion cooperates with the cytoskeleton: adhesion systems can regulate the cytoskeleton with which they are associated and, in turn, those cytoskeletal elements contribute to the biology of adhesion. Accordingly, we have structured our discussion around the individual cytoskeletal systems and focused on solid tissues of the body, particularly epithelia and endothelia, where much of the research on adhesion–cytoskeletal cooperation has been conducted.

Cell–Cell Adhesion and the Actin Cytoskeleton

The F-actin cytoskeleton is necessary for the integrity of many types of cell–cell interactions; this substantially reflects its ability to cooperate with classical cadherin adhesion receptors (Figure 1). Classical cadherins are single-pass transmembrane proteins that engage in homophilic cell–cell adhesion, their cytoplasmic tails directly associate with β -catenin and p120-catenin. β -catenin serves in turn as an anchor for α -catenin, thereby forming a quaternary complex that is commonly called the cadherin–catenin complex (Niessen *et al.*, 2011; Takeichi, 2014). However, many other proteins can interact directly or indirectly with cadherins, although often in a sub-stoichiometric fashion, implying that their recruitment may be subject to cellular regulation.

Integrating Classical Cadherin Adhesion with the Actin Cytoskeleton

Different tissues express different members of the classical cadherin protein family, such as E-cadherin (epithelia), N-cadherin (neurons and mesenchymal cells), and VE-cadherin (endothelia) (Niessen *et al.*, 2011; Takeichi, 2014).

Although it is commonly believed that most, if not all, classical cadherins interact with F-actin, this process has been best studied in epithelia and endothelia. In those confluent tissues, a variety of F-actin networks interact with cadherins, depending on the tissue type being studied and its developmental or functional context. F-actin often concentrates at the cortex of the junctions where cadherins accumulate, as is seen in many simple and stratified epithelia and endothelia (Shewan *et al.*, 2005; Smutny *et al.*, 2010; Huveneers *et al.*, 2012). Similarly, N-cadherin accumulates at the tips of actin-rich dendritic spikes in neurons (Abe *et al.*, 2004; Chazneau *et al.*, 2015). As well, more distinctive patterns of F-actin organization are seen in specialized cellular locations. In simple epithelia, a subpopulation of E-cadherin is stabilized in a specialized junction, the zonula adherens (ZA), which is located at the apical region of cell–cell contacts (Meng *et al.*, 2008). At the ZA, E-cadherin localizes with cortical F-actin and also F-actin bundles that accumulate parallel to the junction itself (Kovacs *et al.*, 2011). In other circumstances, endothelial and epithelial cells can also display F-actin bundles that are

Figure 1 Interactions between classical cadherins and the actin cytoskeleton. Classical cadherins can associate with cortical F-actin through α -catenin, actin-binding proteins that are recruited by α -catenin (EPLIN, vinculin) and by other proteins that can potentially interact with the cadherin cytoplasmic tail (Myosin VI). Junctional actin networks can incorporate Myosin II to form contractile apparatuses.

oriented perpendicular to the cell–cell junctions and terminate in puncta of cadherin (Kwiatkowski *et al.*, 2010; Huveneers *et al.*, 2012; Taguchi *et al.*, 2011). Cortical junctional patterns of F-actin can be converted into perpendicular actin bundles (Taguchi *et al.*, 2011), but the precise mechanisms that control this organizational change are poorly understood. Finally, actin networks (often described as medial-apical networks) have been identified at the apical poles of embryonic epithelia and extend to associate with cadherin junctions (Roh-Johnson *et al.*, 2012; Rauzi *et al.*, 2010).

The F-actin networks that interact with cadherin junctions also associate with a range of other proteins (Figure 1). In particular, non-muscle myosin II interacts with these networks, decorating bundles and cortical F-actin networks both at junctions and the medial-apical poles of cells (Shewan *et al.*, 2005; Smutny *et al.*, 2010; Rauzi *et al.*, 2010). Thus, the actin networks that interact with cadherin junctions often represent actomyosin contractile apparatuses, which can exert force on the junctions. Contractile force is manifest as cellular-scale tension in the junctions (Ratheesh *et al.*, 2012; Wu *et al.*, 2014; Fernandez-Gonzalez *et al.*, 2009); as molecular-scale tension upon cadherin itself (Borghi *et al.*, 2012; Conway *et al.*, 2013); and as movements of the junctions that follow contractions in their associated medial-apical actomyosin networks (Rauzi *et al.*, 2010). It is increasingly apparent that mechanical force influences many aspects of cadherin adhesion, suggesting that cadherin junctions may be regarded as contractile structures that couple cells with one another (Gomez *et al.*, 2011; Pruijt *et al.*, 2014). The integration of actomyosin and cadherin junctions reflects: (1) physical connections between cadherin–catenin complexes and actin filaments and (2) the ability of cadherin adhesions to regulate the F-actin cytoskeleton.

Physical connections between cadherins and F-actin

Multiple molecular mechanisms can couple cadherin adhesion complexes to the F-actin cytoskeleton (Figure 1). One of the most intensively studied of those mechanisms involves α -catenin (Maiden and Hardin, 2011), which is a homologue of vinculin that can directly bind to F-actin (Rimm *et al.*, 1995). Taken with its ability to bind β -catenin, this suggested a model where a ternary complex of cadherin, β -catenin and α -catenin represented the minimal mechanism to couple cadherin adhesion and F-actin (Takeichi, 1991). Consistent with this, biological studies indicate that both the F-actin- and β -catenin-binding domains of α -catenin contribute to cell–cell integrity (Kwiatkowski *et al.*, 2010). However, this model proved controversial, because it was difficult to reconstitute the predicted biochemical complex *in vitro* (Yamada *et al.*, 2005; Drees *et al.*, 2005). However, those early studies were performed in solution and it has recently been revealed that force must be applied for the ternary cadherin–catenin complex to stably bind actin filaments (Buckley *et al.*, 2014). This is consistent with increasing evidence that the conformation of α -catenin and its binding interactions can be regulated by mechanical force (Yao *et al.*, 2014; Yonemura *et al.*, 2010). Therefore, α -catenin may provide a ubiquitous pathway for cadherins to associate with F-actin that becomes apparent when under force.

However, α -catenin is not the only mechanism for cadherins to associate with F-actin. α -Catenin can also anchor the association of other F-actin-binding proteins, such as vinculin

(Huveneers *et al.*, 2012; Yao *et al.*, 2014; Yonemura *et al.*, 2010) and epithelial protein lost in neoplasm (EPLIN) (Abe and Takeichi, 2008), thereby indirectly mediating an association with actin filaments. Alternatively, other actin-binding proteins, such as Myosin VI (Maddugoda *et al.*, 2007) and cortactin (Han *et al.*, 2014), can bind directly to the cadherin cytoplasmic tail. Unlike α -catenin, these other actin-binding proteins are not ubiquitous components of the cadherin molecular complex, which suggests that their contribution to cadherin–actin interactions may depend on the functional context of the junctions. Here, too, mechanical force can play an important influence, as illustrated by the observation that contractility promotes the junctional recruitment of both vinculin (Yonemura *et al.*, 2010; Yao *et al.*, 2014; Leerberg *et al.*, 2014) and EPLIN (Taguchi *et al.*, 2011).

Dynamic regulation of the junctional actin cytoskeleton

The F-actin networks that associate with cadherin junctions are dynamic. F-actin is assembled at junctions when they are assembled (Kovacs *et al.*, 2002b; Tang and Brieher, 2012) and even in mature epithelia junctional F-actin undergoes dynamic turnover (Drees *et al.*, 2005; Kovacs *et al.*, 2011). Cadherin adhesion itself influences the junctional cytoskeleton. Ligation of E-cadherin receptors promotes actin assembly at newly forming adhesions (Kovacs *et al.*, 2002b), while the F-actin content at cell–cell junctions is reduced when cadherins are depleted (Wu *et al.*, 2014). This reflects two broad pathways for cadherins to influence the dynamic actin cytoskeleton.

Firstly, cadherins can directly or indirectly recruit regulators of the actin cytoskeleton to the junctional cortex. These include Arp2/3 (actin-related proteins) (Kovacs *et al.*, 2002b; Tang and Brieher, 2012) and formin nucleators (Kobiela *et al.*, 2004; Carramusa *et al.*, 2007), which can initiate the process of actin assembly at junctions. In addition, cadherin junctions recruit modulators of actin assembly, such as α -actinin-4 (Tang and Brieher, 2012), which promotes Arp2/3 activity; N-WASP (Neuronal Wiskott–Aldrich Syndrome protein), which can stabilize nascent filaments (Kovacs *et al.*, 2011); and Ena/VASP (enabled/vasodilator-stimulated phosphoprotein) proteins that promote filament elongation (Scott *et al.*, 2006). Thus, cadherin adhesions provide cortical platforms that localize the many proteins responsible for regulating junctional actin dynamics and organization.

Secondly, cadherin adhesions promote cortical signals that influence actin dynamics. These signals include the Rac GTPase (Kovacs *et al.*, 2002a; Yamada and Nelson, 2007; Lambert *et al.*, 2002), which stimulates Arp2/3-based actin nucleation (Insall and Machesky, 2009), and also the Rho GTPase (Yamada and Nelson, 2007), which can stimulate formins (Chesarone and Goode, 2009). Rho also promotes the activation and recruitment of Myosin II to complete assembly of the actomyosin contractile apparatus (Jaffe and Hall, 2005; Bresnick, 1999).

Many biochemical interactions underlie the ability of cadherin adhesions to recruit actin regulators and their upstream signals. For example, E-cadherin recruits the Arp2/3 complex through the scaffolding protein, cortactin (Han *et al.*, 2014), while α -catenin can recruit formin-1 (Kobiela *et al.*, 2004), vinculin and Ena/VASP proteins (Leerberg *et al.*, 2014), and the Ect2 Rho activator (Ratheesh *et al.*, 2012). How these are

all coordinated has yet to be elucidated, but mechanical force likely contributes; it is increasingly apparent that cadherins play important roles in mechanosensing at cell–cell adhesions (Ladoux *et al.*, 2010). This can be appreciated when force is experimentally applied to cells bearing cadherins, a process that can lead to cell stiffening (le Duc *et al.*, 2010) or changes in cell migration (Weber *et al.*, 2012). This implies that cells possess signaling pathways that allow them to detect, and respond to, force that is applied to cadherins. At native cell–cell contacts, the source of those forces is likely to include contractility generated within neighboring cells themselves (Liu *et al.*, 2010; Maitre *et al.*, 2012). Such contractility will involve the interactions that classical cadherins make with the actomyosin cytoskeleton that we have already discussed. At the molecular level, force can modulate the ability of α -catenin to bind proteins, such as vinculin (Yao *et al.*, 2014), however the pathways responsible for cadherin mechanotransduction have yet to be characterized in detail.

Biological Functions of Cadherin–Actin Interactions

Classical cadherins participate in a wide range of biological processes, including the maintenance of tissue integrity, morphogenesis, cell–cell communication, and contact inhibition of locomotion (Takeichi, 2014). Integration with the actin cytoskeleton contributes to the action of cadherins at many levels, which encompass the strengthening of adhesion and stabilization of cadherin junctions, to cadherin-dependent morphogenetic movements.

Cadherin adhesion and adhesive strengthening

A core function of adhesion molecules is to resist the external forces that tend to break adhesive bonds and cause cell detachment. Adhesion by classical cadherins is mediated by adhesive ligation of their extracellular domains. However, resistance to detachment is also strengthened when the cytoplasmic domain interacts with the actin cytoskeleton. Adhesion is compromised when cadherin receptors are unable to interact with F-actin (Takeichi, 1991; Yap *et al.*, 1997) and also when either actin filament integrity or myosin II function are inhibited (Takeichi, 1991; Smutny *et al.*, 2010). Actomyosin may strengthen cadherin adhesion through cadherin receptor clustering and by modulating cortical tension.

Classical cadherins form lateral clusters of varying size (Iino *et al.*, 2001; Yap *et al.*, 1997), which can strengthen adhesion by increasing the avidity of adhesive binding. Recent superresolution studies suggest a minimal cluster size of ~5–6 individual cadherin molecules which can then be organized into larger-scale groups (Wu *et al.*, 2015) to form puncta that are readily identified by conventional light microscopy. It has been proposed that cadherin ectodomains alone can mediate clustering by establishing a lattice of adhesive (*trans*-) interactions between ectodomains on opposing surfaces and lateral (*cis*-) interactions between those ectodomains on the same cell surface (Harrison *et al.*, 2011; Brasch *et al.*, 2012). However, cytoplasmic interactions also contribute to clustering (Yap *et al.*, 1997), and, indeed, the formation of larger-scale clusters is perturbed when either F-actin or myosin are inhibited (Hong *et al.*, 2013; Wu *et al.*, 2015; Smutny *et al.*, 2010).

Cortical actin networks can promote clustering by acting as corrals that limit lateral diffusion of individual cadherin receptors (Kusumi *et al.*, 2005; Morone *et al.*, 2006; Wu *et al.*, 2015). Interestingly, elemental clusters can be seen even in the absence of adhesive ligation (Wu *et al.*, 2015), suggesting that a cortical actin mesh may serve to generate the minimal clusters of cadherins. In addition, myosin may promote further clustering by cross-linking and condensing actin networks (Backouche *et al.*, 2006; Soares e Silva *et al.*, 2011).

Junctional actomyosin can also influence cadherin adhesion by modulating cortical rigidity. Cells detach by peeling away from adhesive surfaces (Ward *et al.*, 1994) and mechanisms that retard peeling antagonize detachment, thereby promoting adhesion. Actomyosin contributes to rigidity of the cell cortex by cross-linking actin filaments and promoting cortical tension (Salbreux *et al.*, 2012). When coupled to cadherins, cortical actomyosin may then increase rigidity of the junctional membrane and strengthen adhesion.

Cadherin stabilization and junction formation

The actomyosin cytoskeleton also regulates the dynamic turnover of cadherins at cell–cell junctions. Measured by fluorescence recovery after photobleaching, the stability of E-cadherin at junctions requires myosin II and its upstream regulator, Rho (Priya *et al.*, 2013). This may explain why myosin is necessary in simple epithelial cells for E-cadherin to concentrate in the apical junction of the ZA (Smutny *et al.*, 2010). Such stabilization may reflect the ability of actomyosin to limit the lateral diffusion of cadherins in the plasma membrane, both through lateral corrals and also by myosin-dependent cross-linking and actin network condensation. In addition, association with the actin cytoskeleton can retard cadherin endocytosis (Izumi *et al.*, 2004). Association with actin may potentially antagonize cadherin internalization and thereby stabilize E-cadherin at the cell surface.

Junctional contractility and morphogenesis

Cadherin junctions participate in morphogenetic interactions where cells undergo active rearrangements that are driven by actomyosin-based contractility. Here, cadherins serve not only to allow junctions to resist detachment forces, but also to transmit those contractile forces between neighboring cells. We will outline three forms of morphogenetic movement that entail integration of cadherin adhesion with actomyosin contractility.

Firstly, cell sorting is a process in which cell populations within embryos physically segregate away from one another. It is classically illustrated by the ability of cells from different germ layers to associate with other cells from the same germ layer and dissociate from those of other germ layers (Fagotto, 2015). This was long attributed to expression of different classical cadherins, which allows cells to sort out when mixed in tissue culture (Takeichi, 1991). However, the differential binding capacity of cadherin ectodomains is not sufficient to explain the observed sorting behaviors (Niessen and Gumbiner, 2002). Recently, it was revealed that differences in cortical tension, determined by the actomyosin cytoskeleton, also contribute to the segregation of embryonic germ layers (Krieg *et al.*, 2008). Cadherin adhesion may then participate in cell

sorting by transmitting cortical tension between neighboring cells (Maitre *et al.*, 2012).

Secondly, rearrangements amongst morphogenetically active cells also require cadherin-based cell–cell junctions and actomyosin contractility (Guillot and Lecuit, 2013). These types of morphogenetic movements include convergent-extension (Bertet *et al.*, 2004; Blankenship *et al.*, 2006; Sawyer *et al.*, 2011) and cell invagination (Roh-Johnson *et al.*, 2012). These require cadherins to transmit the contractile forces that are the basis for cell-upon-cell locomotion. Another example of cell-upon-cell movement is the process of cell extrusion (Gu and Rosenblatt, 2012), where individual cells are expelled from epithelial monolayers. Extrusion is associated with diverse processes, including apoptosis (Rosenblatt *et al.*, 2001) and the expression of oncogenes (Hogan *et al.*, 2009). While there are likely to be important mechanistic differences between these different forms of cell extrusion, oncogenic extrusion requires cadherin-based cell–cell adhesion in the neighboring cells (Hogan *et al.*, 2009; Wu *et al.*, 2014), while cadherins at the interface between expelled and neighboring cells are cleaved during the extrusion process (Grieve and Rabouille, 2014). As well, contractile events in both the extruded cells and their neighbors drive extrusion (Slattum *et al.*, 2009; Wu *et al.*, 2014; Hogan *et al.*, 2009). This reflects both activation of myosin and also regulation of the actin cytoskeleton to increase the contractile stress that is generated at the cell–cell interface where extrusion occurs (Wu *et al.*, 2014).

Finally, coupling of cadherin adhesion to contractility also contributes to morphogenetic shaping of whole tissues. This is exemplified by the process of apical constriction (Sawyer *et al.*, 2010), where contractility at the apical poles of epithelial cells allows tissues to be bent and folded, leading to the formation of tissue furrows and invaginations. Physical coupling of cadherins to actomyosin is necessary to transmit the forces that drive invagination (Sawyer *et al.*, 2009; Martin *et al.*, 2009). Of note, coupling of actomyosin to adherens junctions can be a developmentally regulated process that initiates apical constriction (Roh-Johnson *et al.*, 2012); this illustrates the potential for the integration of cadherins and actomyosin to be rate-limiting during morphogenesis. Similarly, cadherin junctions integrate patterns of cellular contractility to yield anisotropic tissue-level patterns of tension during development (Martin *et al.*, 2010). To date, the contribution of cadherins to generating morphogenetic forces has principally focused on the capacity of cadherins to passively couple the contractile apparatuses of cells together. However, as we have discussed, cadherin adhesion can also promote the biogenesis of junctional actomyosin by promoting actin assembly and supporting Rho associated protein kinase (ROCK) signaling (Ratheesh *et al.*, 2012), while cortical stiffening elicited by cadherin mechanotransduction is likely to influence morphogenesis (le Duc *et al.*, 2010). It remains to be determined whether this active contribution of cadherins to cellular contractility participates in morphogenesis.

Cell–Cell Adhesion and the Intermediate Filament Cytoskeleton

IFs associate with desmosomes (Figure 2), specialized cell–cell junctions that are found in many solid tissues, including both

Figure 2 Association of desmosomes with IFs. Desmosomes comprise desmosomal cadherins (desmogleins and desmocollins) that associate with Pg and members of the Pkp family, which anchor Dp to bind IFs.

simple and stratified epithelia and cardiac muscle. An analogous junction that interacts with IF in endothelia is called the complexus adhaerentes and shares molecular similarities with desmosomes. IFs are believed to provide mechanical stability for cells (Gruenbaum and Aebi, 2014) and coupling of IF to desmosomes can then extend mechanical stabilization by IF to the tissue level. Indeed, as we shall see, the functional impact of linking desmosomes to IF is especially apparent in tissues that are subject to mechanical stress, such as the epidermis and cardiac muscle.

Integrating IFs and Desmosomes

Adhesion by desmosomes is mediated by distinct members of the cadherin superfamily. There are two classes of desmosomal cadherins, desmogleins and desmocollins, and each of these classes contains several isoforms (Delva *et al.*, 2009). The specific desmogleins and desmocollins that are expressed in cells vary with their tissue of origin. Nonetheless, mature, functionally competent desmosomes require at least one member from each of the desmosomal cadherin family, leading to the suggestion that they may involve heterodimers of desmocollins and desmogleins.

The cytoplasmic tails of the desmosomal cadherins associate with a range of cytoplasmic proteins to form plaques that link desmosomes to IF (Johnson *et al.*, 2014; Figure 2). This physical linkage is mediated by two sets of proteins (Nekrasova and Green, 2013). First, proteins of the armadillo family, plakophilins (Pkp) and plakoglobin (Pg), interact directly with the desmosomal cadherins. These armadillo family proteins then anchor desmoplakin (Dp), which can associate directly with IFs, thereby completing the physical association between desmosomal cadherin receptors and IF. Interestingly, Dp is common to all tissues where cell–cell adhesion is linked to IF (Johnson *et al.*, 2014). In contrast, the desmosomal cadherin isoforms and armadillo plaque proteins that are used for adhesion vary significantly between tissues.

The C-terminus of Dp mediates its interaction with IF. Of note, IF proteins show great diversity, being encoded by a large (70 member) family of genes with a common domain

organization, but highly divergent primary sequences whose complexity is further increased by alternative splicing (Herrmann *et al.*, 2009). IF proteins are differentially expressed during development and in different tissues. To date, desmosomes have been reported to interact with a number of the major IF proteins, including keratin, desmin, and vimentin (Green and Simpson, 2007). For example, in cardiac myocytes desmosomes associate with desmin, whereas complexus adherente in endothelia interact with vimentin (Getsios *et al.*, 2004). This degree of cell type specificity may reflect the major IF genes that are expressed, although additional levels of regulation are possible.

Physiological Functions of Desmosomal-IF Integration

The necessary role that desmosomes play in maintaining tissue integrity is well illustrated by diseases that target desmosomal proteins in stratified epithelia of the skin and mucosal membranes. For example, patients with the skin diseases pemphigus vulgaris and pemphigus foliaceus produce autoantibodies that target desmogleins 1 and 3 (Green and Simpson, 2007). These inhibit desmosomal adhesion causing loss of cell–cell adhesion (acantholysis) that manifests as blistering of the skin and mucosae. One mechanism for these autoantibodies to disrupt adhesion is by inducing the down-regulation of Dsg expression on the cell surface through endocytosis (Delva *et al.*, 2008). Human genetic diseases also provide compelling evidence that their interaction with IF is necessary for desmosomes to support tissue integrity. For example, severe acantholysis bullosa and extensive skin erosion were reported to be due to compound heterozygous mutations that truncated the IF-binding C-terminus of Dp (Delva *et al.*, 2008). Similarly, mutations in IF genes are associated with skin blistering and loss of adhesion. This implies that integration of desmosomes and IF is necessary to allow the epidermis to resist mechanical stresses.

Several distinctive biophysical properties of desmosomal adhesion and IF may cooperate to confer resistance to stress. Firstly, desmosomal cadherins display the phenomenon of 'hyper-adhesion' (Garrod and Tabernero, 2014). Whereas initial adhesion by desmosomes requires extracellular calcium, as desmosomes mature they display increased stability and adhesive strength and become resistant to the removal of calcium (Kimura *et al.*, 2007). In contrast, classical cadherins do not display 'hyper-adhesion' and remain dependent on extracellular calcium. Hyper-adhesion is a regulated process that responds to Protein Kinase C- α (PKC- α), as desmosomes remain hyper-adhesive when PKC- α is depleted (Johnson *et al.*, 2014).

IF also display distinctive biophysical properties that allow them to resist mechanical stress (Herrmann *et al.*, 2007). Firstly, individual IFs are soft and flexible, in contrast to actin filaments and MTs which readily break upon stress. However, high concentrations and cross-linking can significantly increase the stiffness of the IF network, into the MPa–GPa range, as found in skin and hair, respectively. Secondly, IFs are much more extensible than other cytoskeletal elements, single keratin filaments being able to be stretched up to 3.5-fold before breaking. Finally, IF undergo hardening when strain is applied, a property that is unique to IF and confers greater resistance to breakage than actin filaments or MTs. It seems likely that these physical

properties of IF cooperate with hyper-adhesion by desmosomes to confer a unique capacity to resist mechanical stresses.

Finally, in addition to conferring resistance to mechanical stress, desmosomes also influence cell proliferation and differentiation by regulating cell signaling pathways (Green and Simpson, 2007). These effects have principally been studied by manipulating the functional of desmosomal cadherins and their associated proteins. However, it is possible that association with IF also contributes by regulating desmosomal assembly and dynamics (Getsios *et al.*, 2004). For example, keratins modulate Dp phosphorylation by PKC- α to influence desmosomal stability (Johnson *et al.*, 2014).

Cell–Cell Adhesion and MTs

In contrast to the well-established contributions of F-actin and IF to cell–cell adhesion, the interrelationship between cell adhesion and the microtubule cytoskeleton is an emerging area. MTs are dynamic, polarized polymers of tubulin. The polarity of MTs is reflected in their free ends (typically called the plus and minus ends), which differ in dynamics and interacting proteins; polarity also encompasses the MT lattice itself to allow the directed movement of motor proteins with a preference to move to either the plus or minus end. Many MTs are anchored by their minus ends at the perinuclear centrosome (called centrosomal MTs) and extend with their plus-ends directed outwards. In addition, non-centrosomal MTs are also found, which are not anchored at the centrosomes.

Linkages between MTs and Cell–Cell Junctions

MTs can interact with both classical cadherins at adherens junctions and with desmosomes (Figure 3). Non-centrosomal MT have been found to concentrate at cell–cell junctions both in simple and stratified epithelia (Bacallao *et al.*, 1989; Lechler and Fuchs, 2007; Stehbens *et al.*, 2006; Bellett *et al.*, 2009). In simple polarized epithelia, these can run in an apical-to-basal direction, with their plus-ends oriented basally (Bacallao *et al.*, 1989). In contrast, MTs appear to align with the X–Y plane of the junctions in the flattened stratified squamous epithelial cells of the epidermis (Lechler and Fuchs, 2007). As well, populations of MTs, some of which may be anchored at centrosomes, have been identified which extend with their plus-ends directed toward the junctional cortex (Stehbens *et al.*, 2006). The precise pattern of MTs that interacts with junctions may depend on the developmental context of the cells. For example, as cultured epithelial cells first make contacts with one another, centrosomal arrays tend to predominate, extending their plus-ends toward the junctions, to be replaced by non-centrosomal junctional arrays as the monolayers mature and polarize (Bellett *et al.*, 2009). Similarly, centrosomal arrays predominate in the basal layer of the skin to be replaced by non-centrosomal junctional MTs in the suprabasal layers (Lechler and Fuchs, 2007). What controls these changes in organization of MTs relative to junctions is not yet understood, but may reflect the impact of cell polarization on cytoskeletal organization (Bryant and Mostov, 2008).

These different patterns of association between MTs and junctions are likely to reflect the different classes of MT-

Figure 3 Interactions between MTs in epithelial cells. MTs are organized as centrosomal and non-centrosomal arrays which can interact with cell-cell junctions. At adherens junctions, classical cadherin/catenin complexes can interact with a range of MT-binding proteins, such as CAMSAP3/Nezha, CLASP2, kinesins, and dynein. Desmosomal cadherins can recruit MT-binding proteins such as CLIP190 and ninein.

binding proteins that can interact with either classical cadherin adhesions or desmosomes (Figure 3). Desmosomes can recruit the minus-end binding protein, ninein, through a biochemical interaction with desmoplakin (Lechler and Fuchs, 2007). Ninein is also found at centrosomes but relocalizes to accumulate at cell-cell junctions as epidermal cells differentiate. This coincides with the accumulation of non-centrosomal MTs at junctions (Lechler and Fuchs, 2007). Dynein, a minus-end directed motor, can be found at E-cadherin junctions, where it associates with β -catenin (Ligon *et al.*, 2001). Calmodulin-Regulated Spectrin-Associated Protein 3 (CAMSAP3, originally called Nezha) is a minus-end binding protein that is recruited to E-cadherin adhesions in simple epithelial cells by a complex that consists of the scaffolding protein, Pleckstrin homology domain-containing family A member 7 (PLEKHA7), which binds directly to p120-catenin (Meng *et al.*, 2008). In keratinocytes p120-catenin also binds directly to cytoplasmic linker associated protein 2 (CLASP2), a plus-end binding protein, providing a mechanism to capture MT plus-ends at adherens junctions (Shahbazi *et al.*, 2013).

MT-binding proteins can influence the interactions between MT and junction by mediating physical associations and/or influencing MT dynamics. For example, when anchored to E-cadherin, dynein can potentially bind to MTs and exert force to anchor them to the junctions (Ligon *et al.*, 2001). On the other hand, both CAMSAP3 and ninein can anchor and stabilize the minus ends of MTs (Meng *et al.*, 2008; Lechler and Fuchs, 2007). As MTs grow preferentially from their plus-ends, anchorage of their minus ends at junctions can serve to determine where they assemble and thereby influence their junctional accumulation.

Functional Contributions of MTs at Junctions

MT integrity and dynamics are necessary for the integrity of cell-cell adhesive junctions. The integrity of the ZA in simple epithelial cells is compromised when MTs are depolymerized with drugs, such as nocodazole; when the dynamic behavior of their plus-ends is inhibited, either using low concentrations of nocodazole or by inhibiting proteins that associate with dynamic plus-ends; and when minus-end anchorage via CAMSAP3 is perturbed (Stehbens *et al.*, 2006; Meng *et al.*, 2008). Similarly, the ability to form stable desmosomes was compromised in keratinocytes depleted of LIS1 (Sumigra *et al.*, 2011). In the latter case, the defect in desmosomal biogenesis was accompanied by a compromised epithelial barrier and terminal differentiation of keratinocytes. These functional effects may reflect several ways in which interactions with MTs can affect cell-cell junctions.

MT-dependent cellular transport

MTs are major mechanisms for the active transport of vesicles, organelles and molecular complexes. Such transport is mediated by the MT-dependent motors, dynein and kinesins. Therefore, the anchorage or assembly of MTs at junctions could provide a mechanism to facilitate the transport of cortical and membrane components to the junctions. Consistent with this, the minus-end directed motor, Kinesin superfamily protein 3 (KIFC3), accumulated at junctions in epithelial cells and this required anchorage of MTs at their minus ends via CAMSAP3 and PLEKHA7 (Meng *et al.*, 2008). Further, many specialized junctional components, including classical cadherins, desmosomal cadherins, and gap junction elements, are

transported to cell–cell junctions by MT-dependent motors (Bryant and Stow, 2004; Shaw *et al.*, 2007; Nekrasova and Green, 2013; Chen *et al.*, 2003). This can facilitate both the assembly of junctions and their maintenance, as junctional components undergo endocytosis and turnover in established epithelia (Bryant and Stow, 2004). Indeed, junctions are depleted when their transporting MT-based motors are inhibited. Thus, the delivery of junctional components represents one mechanism for MTs to support cell–cell junctions.

Alternatively, MT-based transport can indirectly affect junctional integrity by regulating the turnover of junctional components. For example, KIFC3 can transport Ubiquitin-specific protease (USP) 47 to junctions; this enzyme catalyzes the removal of ubiquitin from proteins and may protect E-cadherin from degradation (Sako-Kubota *et al.*, 2014).

Regulation of cortical signaling

MTs can also influence cortical signaling by diverse pathways. One example involves the Rho GTPase, although the impact of MTs differs depending on the biological context. Epithelial cell–cell junctions are sites where Rho signaling is activated to stabilize adhesion and promote contractility (Ratheesh *et al.*, 2012). In cultured mammalian epithelial cells, dynamic MTs can support junctional Rho signaling (Ratheesh *et al.*, 2012), whereas in embryonic *Drosophila* epithelia dynamic MTs appear to antagonize Rho signaling (Bulgakova *et al.*, 2013). This appears to reflect different impacts of MTs upon the molecular machinery that regulates Rho signaling. In mammalian cells, dynamic MTs facilitate the junctional recruitment of the centralspindlin complex, a cytokinetic regulator that is also found at junctions of interphase epithelial cells. Centralspindlin promotes Rho signaling by recruiting and activating the Rho Guanine nucleotide exchange factors (GEF), Epithelial cell transforming sequence 2 protein (Ect2) (Ratheesh *et al.*, 2012). In contrast, in the embryonic *Drosophila* epithelium, dynamic MTs appeared to antagonize another Rho activator, DRho-GEF2, thereby reducing Rho activity (Bulgakova *et al.*, 2013). By another mechanism, MTs can sequester the Rho GEF-H1 preventing it from stimulating Rho; however, MT depolymerization can stimulate Rho signaling when GEF-H1 is released (Krendel *et al.*, 2002). Understanding the basis for these context-dependent differences will therefore rely upon elucidating how dynamic MTs control these upstream regulators of Rho.

Concluding Comments

In summary, cytoskeletal connections play intimate roles in the biology of cell–cell adhesions. It is useful to consider cell–cell junctions as the product of integrating adhesion with the cytoskeleton. As we have illustrated in our current discussion, such integration involves the coordination of dynamic adhesive and cytoskeletal systems. While we have focused on the individual cytoskeletal systems and their associated adhesive junctions, it is important to emphasize that cross talk between these systems can occur at many levels. Firstly, cell signaling can link different junctional and cytoskeletal systems to one another. For example, regulation of cortical Rho signaling by dynamic MTs can affect actomyosin-based contractility at cell–cell junctions (Ratheesh *et al.*, 2012). Secondly, regulation

of junctional actin and its coupling to cadherins can potentially recruit other adhesion systems. As an example, classical cadherins can recruit nectins into maturing adherens junctions, through their capacity to interact with α -catenin (Trojanovsky *et al.*, 2015). Finally, different cytoskeletal networks may be physically and/or functionally linked together. For example, formins can regulate both actin and MT dynamics (Palazzo *et al.*, 2001); proteins like spectroplakins can link MTs, MFs, and IFs (Huelsmann and Brown, 2014); and IFs are implicated in force sensing by classical cadherins (Weber *et al.*, 2012). How these, and other modes, of cross talk influence the integration of cell–cell adhesion and the cytoskeleton will be an interesting topic of research for the future.

Glossary

Integrins A diverse family of adhesion receptors, mediating cell–matrix or cell–cell contacts. Integrins are heterodimeric transmembrane receptors consisting of α and β chains; in combination, they define the specificity of the adhesive interaction at the cell's exterior, and the local interaction with the cytoskeleton within the cells.

Invadopodia Protrusive cell adhesions associated with cancer cell invasion and metastasis. Invadopodia consist of an integrin-based adhesion domain through which they are attached to the matrix, a protrusive, actin-rich domain, and a proteolytic domain, responsible for local degradation of the matrix.

The Extracellular Matrix (ECM)

The ECM is composed of fibrillar networks that serve as scaffolds on which and within which tissue cells live (Hay, 1991; Alberts *et al.*, 2007). Interaction with the ECM affects the survival, proliferation, differentiation, and migration of individual, the so-called ‘anchorage dependent’ cells (Stoker *et al.*, 1968). In intact tissues it supports structural stability, sustains functional homeostasis and regulates the fate and behavior of the constituting cells (Davis and Camarillo, 1995; Menko and Boettiger, 1987). Adhesion-mediated signaling is based on the capacity of cells to sense and respond to changes in the chemical and physical properties of the ECM (Watt and Driskell, 2010) in a wide variety of processes, including embryonic development, tissue remodeling, and wound healing, as well as in disease states such as cancer invasion and metastasis (Egeblad *et al.*, 2010a,b). However, despite the strong evidence for physiological cell-ECM cross-talk *in vivo*, the molecular mechanisms underlying adhesion-dependent signaling, are poorly characterized, most likely due to the chemical and physical diversity and molecular complexity of living organisms (Hynes and Naba, 2012). Thus, many studies addressing adhesion-mediated processes are conducted *ex vivo*, enabling the design and fabrication of matrices with well-defined properties. In this chapter we will primarily address the mechanisms underlying cell adhesion to the ECM in such well-defined culture conditions.

Indeed, the ECM is highly diverse in structure, ranging from loose connective tissue to densely packed tendons, and sheets of basement membrane. Its variability can mainly be attributed to distinct molecular compositions and postdeposition remodeling. Connective tissue fascia and tendons, for example, contain high levels of collagen I, while basement membranes are enriched with collagen V, laminin, and different proteoglycans (Ricard-Blum, 2011; Yurchenco, 2011). Especially interesting is the fact that in addition to scaffolding networks, the ECM is loaded with growth factors (e.g., fibroblast-, transforming- and heparin-binding epidermal growth factors) that associate with specific components of the matrix (e.g., heparin sulfate proteoglycan) and stimulate the nearby adhering cells (Gospodarowicz *et al.*, 1980; Hay, 1991; Hynes, 2009; Munger and Sheppard, 2011; Sarrazin *et al.*, 2011). This process, whereby the ECM serves as a spatially defined signaling environment, is being applied as a powerful tool for culturing tissue cells under close-to-native conditions, *ex vivo*.

Another feature of the ECM that affects the attached cells is its dimensionality. Thus, cells can differentially respond through adhesion to one-dimensional (1D) matrices dominated by elongated fibrils (Doyle *et al.*, 2009); two-dimensional (2D) matrices such as basement membranes; and three-dimensional (3D) matrices, in which the cells are totally or partially embedded in the matrix (Cukierman *et al.*, 2001; Elsdale and Bard, 1972; Nelson and Bissell, 2006). Recent studies have demonstrated that cells can respond to the microtopography or even nano-topography of the surface to which they adhere (Baharloo *et al.*, 2005; Cukierman *et al.*, 2001; Curtis and Wilkinson, 1997; Geblinger *et al.*, 2010; Geiger *et al.*, 2001; Grossner-Schreiber *et al.*, 2006; Vogel *et al.*, 2006). Nano-patterning technologies have also been utilized to test the capacity of cells to recognize particular spacings between adhesive ligand epitopes, thus demonstrating that cells require certain threshold ligand proximities, usually within the range of a few tens of nanometers, for stimulating cell spreading and cytoskeletal reorganization (Cavalcanti-Adam *et al.*, 2007; Geiger *et al.*, 2009; Grinnell and Petroll, 2010; Massia and Hubbell, 1991; Yamada and Cukierman, 2007).

Diversity of ECM Adhesions

Clearly defined adhesions with the ECM are formed by essentially all adherent animal cells, in culture and *in vivo*; yet their molecular composition, subcellular distribution, size, and morphology can be quite heterogeneous. Particularly widespread and important are focal adhesions, usually located near the cell periphery, and associated with bundles of actin microfilaments (Geiger *et al.*, 2009; Figure 1). Focal adhesions share certain features in common: they are oval structures, several square microns in size, that are mediated by integrins, and interact with the actin cytoskeleton at the inner aspects of the membrane. Their development is stimulated by the small GTPase Rho, and requires actomyosin contractility. Characteristic focal adhesion plaque proteins include vinculin, paxillin, talin, and tyrosine-phosphorylated proteins. Interestingly, the molecular composition of the ECM (e.g., fibronectin vs. vitronectin or laminin) and the cellular interactions with these matrices via different integrins (e.g., $\alpha_5\beta_1$ vs. $\alpha_v\beta_3$) lead to the formation of focal adhesions of distinct morphology, size, and subcellular distribution (Figure 2). Focal adhesions are

Figure 1 (a) Focal adhesions (red) are usually located at the cell periphery, anchoring contractile actin bundles (green), termed ‘stress fibers,’ to the ECM. (b) Electron microscope image showing a side view of the cell edge (e.g., dashed line in (a)). From bottom to top: ECM (dense patches), cell membrane (continuous line), actin fibers associated with focal adhesions (sparse patches next to cell membrane), microtubules, and cell organelles.

mainly prominent in cultured cells growing on solid surfaces; yet structures with similar molecular properties are also found *in vivo* (e.g., myotendinous junctions, adhesions to the basement membrane). One clear example for *in vivo* analogs of focal adhesions is the dense plaque of smooth muscle tissues, which is the anchorage site of the contractile actin machinery to the plasma membrane. This was demonstrated both by antibody labeling of smooth muscle sections, which displayed an abundance of adhesion components in these sites (North *et al.*, 1993; Winograd-Katz *et al.*, 2014), and by cryo-electron tomography (Bokstad *et al.*, 2012), which revealed, in these sites, specific focal adhesion-associated particles (Patla *et al.*, 2010).

Another form of integrin adhesion is focal complexes, small (around 100 nm in diameter), dot-like structures that are primarily located along the lamellipodium’s edge (Zamir and Geiger, 2001; Figure 3(a)). These sites can be associated with cell migration, or serve as precursors of focal adhesions. Their formation is induced by the Rho family GTPase Rac. In the more central locations of many cell types, ‘fibrillar adhesions’ (known also as ‘ECM contacts’), dot-like or elongated structures associated with ECM fibrils, are also found (Zamir *et al.*, 2000; Figure 3(b)). Fibrillar adhesions are typically associated with ‘soft’ extracellular fibronectin fibrils, mediated by the fibronectin receptor $\alpha_5\beta_1$ integrin, and enriched with the cytoplasmic protein tensin. Fibrillar adhesions emerge from focal adhesions in an actomyosin-dependent fashion. Another form of ECM adhesion is the invadosome, including podosomes and invadopodia, small (around 0.5 μm in diameter) cylindrical structures consisting of typical focal adhesion proteins, including vinculin and paxillin (Linder, 2009; Revach and Geiger, 2014). Podosomes are found in cells such as macrophages and osteoclasts (Figure 4(a)), whereas invadopodia are

Figure 2 The molecular composition of the ECM (here, the glass surface is coated with fibronectin or vitronectin) and the cellular interaction with these matrices via different integrins ($\alpha_5\beta_1$ and $\alpha_v\beta_3$, respectively) lead to the formation of focal adhesions (stained here for vinculin and paxillin) with distinct morphology, size, and subcellular distribution. Images courtesy of B. Zimmerman.

predominantly found in invasive or metastatic cancer cells (Figure 4(b)). Characteristic proteins, indispensable for invadosome formation are gelsolin and dynamin, both of which localize to the actin cores of these structures.

It is noteworthy that most of the matrix adhesions described above, interact, through their cytoplasmic aspects, with the actin cytoskeleton. Nevertheless, the adhesion of epithelial cells to the underlying basement membrane is also mediated by another class of adhesions, known as hemidesmosomes, which typically associate, within the cell, with the keratin-based intermediate filament system. The primary integrin that mediates these interactions is $\alpha_6\beta_4$, which is accompanied, in some tissues, by additional transmembrane matrix receptors as well (Litjens *et al.*, 2006). The third cytoskeletal network, microtubules, is apparently not associated directly with matrix adhesions, yet it has been shown that microtubules negatively regulate focal adhesion stability (Bershadsky *et al.*, 1996; Kaverina *et al.*, 1999). In addition, podosomes in osteoclasts and other cell types depend on the presence of intact microtubules, and dissociate upon cell treatment with microtubule-disrupting drugs (Destaing *et al.*, 2003, 2005).

The Integrin Adhesome

The molecular components of the adhesion machinery, consisting of over 200 distinct proteins that localize to focal

Figure 3 (a) Focal complexes (arrow) are small (~ 100 nm in diameter), dot-like adhesions primarily located near the lamellipodium edges. These sites can serve as precursors of focal adhesions (arrowhead), and may be involved in cell migration. (b) Fibrillar adhesions are dot-like or elongated structures, and associated with ECM fibrils located near the cell center in various cell types.

Figure 4 Invadosomes, including podosomes and invadopodia, are small (~ 0.5 μ m in diameter) cylindrical adhesion structures consisting of focal adhesion proteins such as vinculin (red) surrounded by an actin core (green). (a) Podosomes (arrow) at the periphery of an osteoclast. (b) Invadopodia (arrow) are prominently found in the vicinity of the cell nucleus in invasive or metastatic cancer cells. adhesions either constitutively or transiently, are known, collectively, as the ‘integrin adhesome’ (Zaidel-Bar and Geiger, 2010; Zaidel-Bar *et al.*, 2007). An updated list of components, available in (Winograd-Katz *et al.*, 2014) can be divided into two major domains: a ‘scaffolding domain,’ consisting of the adhesion receptors (mostly different integrins), a multitude of adapter proteins that connect the receptors to the cytoskeleton, and various actin-binding and regulatory proteins. In addition, a ‘regulatory domain’ consisting of a multitude of signaling proteins (e.g., kinases, phosphatases, G-proteins and their activators or inhibitors), generates and mediates adhesion-dependent signaling cascades, thereby affecting cell behavior, as well as the development and modulation of the adhesions themselves (Figure 5).

The transmembrane components of focal adhesions contain different pairs of α - and β integrin subunits, which bind to specific matrix components via their extracellular domains (Giancotti and Ruoslahti, 1999). The matrix specificity of cells is primarily attributed to the type of integrin they possess, and to their state of activation. The most common integrins found

in focal- and related ECM adhesions are the fibronectin receptor, $\alpha_5\beta_1$, and the vitronectin receptor, $\alpha_v\beta_3$. Additional membrane receptors, though less characterized at the structural and functional levels, include other integrins, as well as potentially adhesive molecules such as syndecan-4 and the hyaluronan-binding protein layilin (Lanza *et al.*, 2013).

Associated with the cytoplasmic aspect of the plasma membrane is the focal adhesion plaque, consisting of multi-protein complexes that interact with the cytoplasmic tails of the integrin chains and, eventually, link them to the actin cytoskeleton. Some of these plaque components, including α -actinin, talin, filamin, and tensin, contain binding sites for both integrins and actin, while other integrin-associated molecules do not directly bind to actin, but rather to different actin-associated proteins or additional ‘adapter’ proteins. Notably, these adapters, which include signaling proteins such as focal adhesion kinase (FAK), the LIM-domain protein DRAL, or adhesion mechano-regulators such as vinculin, can play regulatory roles. In fact, vinculin plays a pivotal role as a central linker interacting with many plaque proteins, including

Figure 5 Diagram depicting the different functional and chemical groups comprising the integrin adhesome. Some 232 distinct proteins and other molecules are known to be contained in, or directly associated with, focal adhesions and other, similar adhesion sites. The adapter proteins, together with the actin regulators, form the scaffolding domain of the adhesion site, providing it with its unique mechanical properties. The stability and dynamics of the adhesion are controlled by its regulatory components, which include diverse elements of signaling cascades, mostly kinases and their corresponding phosphatases, as well as small Rho GTPases and their GEF and GAP regulators.

talin, α -actinin, VASP/Ena, ponsin and vinexin, as well as with acidic phospholipids and actin. Taken together, the adapter components and actin regulators of focal adhesions form the 'scaffolding domain' of the adhesion site, and generate the unique mechanical properties of these structures. Furthermore, many signaling molecules were shown to interact with these adhesions, and regulate their stability and dynamics. These 'regulatory components' include diverse components of signaling cascades, mostly kinases (tyrosine- and serine/threonine-specific) and the corresponding phosphatases, as well as small Rho GTPases and their GEF and GAP regulators. It is likely that dynamic, continuous cross-talk between the scaffolding and signaling domains is responsible for both the global 'adhesion-mediated signaling' believed to be generated in focal adhesions, as well as for the local dynamic reorganization of the adhesion sites in which they reside. Further details about the interplay between these two functional domains of adhesion sites are described in (Zaidel-Bar and Geiger, 2010).

Geometric and Mechanical Sensory (Mechanosensing) Functions of ECM Adhesions

The ECM presents cells with highly complex and diverse physical environments. Different tissue types may vary dramatically in rigidity (bone vs. cartilage), activity (beating heart vs. static brain), and geometry (2D basement membrane vs. 3D stroma), all of which influence cell organization and

function. Over the past two decades, a number of physical features of the cellular microenvironment have been observed, primarily *ex vivo*, to play key biological roles:

- **Spatial distribution of ECM ligand molecules:** The spacing of ECM ligands in physiological conditions may vary greatly. To mimic such conditions, cultured cells were plated on 2D substrates with controlled, nanoscale-positioning of the ECM ligands (Arnold *et al.*, 2008). Cells spread and migrated on the nanopatterned surfaces when ligand spacing was below a critical value (~ 70 nm), while at higher spacings, cell viability was severely hampered, eventually leading to apoptosis. Moreover, cells could detect and respond to minute gradients in ligand spacing (comparable to ligand positioning inhomogeneities), indicating that the ECM cues were averaged over a number of adhesion sites, to improve cellular sensitivity. Notably, an intrinsic focal adhesion length scale was observed in the same range as that of 'optimal' ligand spacing (Patla *et al.*, 2010). Three-dimensional structural reconstruction of focal adhesions using cryo-electron tomography revealed particles located at the cell membrane, and attached to actin fibers with a mean interspacing of approximately 45 nm.
- **ECM geometry:** The ECM provides cells with a 3D microenvironment. However, in some cases, the effective cell-matrix contacts are geometrically confined. For example, epithelial and endothelial cells adhere to the basal lamina, a practically 2D substrate (Stamenovic *et al.*, 2009). In addition, cells adhering to single ECM filaments effectively sense a 1D geometry (Sharma *et al.*, 2012). *In vitro* studies

- mimicking these different geometries have demonstrated particularly diverse cell shapes, polarities and migration speeds (e.g., Doyle *et al.*, 2009). In addition, the porosity level of the 3D ECM scaffold was shown to influence cell morphology and migration dynamics (e.g., ameboid vs. mesenchymal motion, and individual vs. collective migration) (Friedl and Gilmour, 2009).
- ECM topography: While the vast majority of cell culture studies are conducted, for imaging purposes, on flat substrates, cells *in vivo* adhere to rough surfaces as well. In such cases, the cell membrane can bend and deform to remain in contact with the ECM. In turn, the resulting curvature of the cell membrane and adhesion sites may affect cell behavior, by exposing cryptic protein binding sites or activating mechanosensitive ion channels (Hoffman *et al.*, 2011). One example of the correlation between surface roughness and cell response was observed in bone-resorbing osteoclasts, in which the resorption dynamics are highly dependent on ECM topography (Geblinger *et al.*, 2010).
 - ECM rigidity: *In vivo*, ECM rigidities span over 7 orders of magnitude, with different cell types typically associated with characteristic stiffness regimes (Discher *et al.*, 2005; Swift *et al.*, 2013). Loss of the cell's ability to sense changes in ECM rigidity are associated with cell dysfunction and disease (Janmey and Miller, 2011). For example, tumor stroma is typically stiffer than normal stroma, and its progression in 3D models correlates with ECM rigidity. In 2D cultured systems, substrate rigidity has been associated with cell morphology (Geiger *et al.*, 2009; Vogel and Sheetz, 2006), migration (Lo *et al.*, 2000; Saez *et al.*, 2007), proliferation (Janmey and Miller, 2011; Orr *et al.*, 2006), gene expression and differentiation (Discher *et al.*, 2005; Guilak *et al.*, 2009). The mechanism through which cells

probe the rigidity of their microenvironment involves application of actomyosin contractile forces via the cell-ECM adhesion sites, notably focal adhesions.

- External forces: The ECM mechanically couples cells anchored to it. In this manner, cells are exposed to external forces, which may be critical for tissue development, function, remodeling and healing. Remarkably, both constant (e.g., blood flow experienced by endothelial cells) and rhythmic force perturbations (e.g., originating in the respiratory or cardio-vascular systems) have been associated with cell realignment at well-defined and uniform angles (Wang and Grood, 2000).

The Cross-Talk between the Cell and the ECM

The ECM is a highly complex network of adhesive filaments with specialized chemical, mechanical and geometric properties (Geiger and Yamada, 2011). It serves as an effective tissue scaffold, providing cells with the precise environmental conditions required for proper development, survival and proliferation. Similar to the cytoplasmic aspects of focal adhesions described above, the ECM is characterized by both scaffolding and signaling properties. The scaffolding elements attached to the extracellular faces of focal adhesions consist of tightly packed arrays of ECM filaments, which are nearly colinear with the cytoplasmic actin filaments that attach to the focal adhesion at the cell interior (Singer, 1979). In addition, there is ample evidence that the ECM serves as a depot for growth factors that can stimulate the growth, differentiation and dynamics of the attached cells (Brizzi *et al.*, 2012; Gospodarowicz *et al.*, 1980; Hynes, 2009). This combination of external stimulation of adherent cells by chemical and physical

Figure 6 Diagram depicting the cross-talk between cells and the ECM. The properties of the ECM scaffold, such as composition, rigidity, and topography, and associated external forces, induce the formation of cellular adhesion structures (the 'outside-in' effect). The resulting signaling cascades that follow, through the integrin adhesome, may in turn drive an 'inside-out' process of ECM remodeling by the cell. Thus, bi-directional cross-talk between the cell, through its adhesion machinery, and the surrounding microenvironment is perpetually maintained, remodeling the ECM and, in turn, affecting cell behavior, structure, and fate.

ECM-mediated cues is, most likely, underlying the ‘anchorage dependence’ properties of normal cells, which are often lost upon malignant transformation (Stoker *et al.*, 1968).

ECM adhesion sites also serve as major environmental sensors, which are induced to assemble by means of chemical and physical cues generated at their points of contact with the ECM and activating, across the membrane, various signaling cascades that affect cell behavior and fate (Figure 6). Typical signaling events triggered by the adhesion include the activation of tyrosine phosphorylation caused by the accretion and activation of FAK and Src, the activation of Rho and Ras small GTPases, and the subsequent activation of the extracellular signal-regulated kinase (ERK) pathway (Geiger *et al.*, 2009). It is proposed that the tethering of FAK to clustered integrins leads to its autophosphorylation, followed by the recruitment of Src, which binds to phospho-FAK via its phosphotyrosine-binding domain (SH2), and followed by further phosphorylation of a series of downstream targets (Mitra and Schlaepfer, 2006). It is further believed that the local accumulation of a rich variety of kinases, phosphatases and their substrates in the sub-membrane focal adhesion plaque plays a key role in the adhesion-mediated signaling process (Geiger *et al.*, 2009). That said, definitive information concerning these signaling processes and their cellular effects remains scarce. It is interesting to note that, apart from the long-term and long-range adhesion signals that affect overall cell fate, there are also local signals, which act at, and affect focal adhesion structure and stability.

Clearly, however, the ECM scaffold and the sensory-signaling machinery of the cell conduct a complex molecular dialog that has far-reaching consequences for the cells. The focal adhesion-based sensory system is capable of sensing multiple molecular and physical cues such as ligand chemistry and spacing, surface nano-topography, geometry, rigidity and external forces. This rich information is integrated by focal adhesion-associated networks and triggers a cytoplasmic response; a process known as an ‘outside-in response.’ In turn, the same signaling cascades, triggered by environmental cues, can induce an ‘inside-out response,’ modifying the neighboring ECM (e.g., through dissolution with proteases, mechanical perturbation, or additional fiber deposition) which, in turn, can affect the original environmental signals. It is proposed that this bi-directional cross-talk between the cell, through its adhesion machinery, and the microenvironment is perpetually maintained, remodeling the ECM and, in turn, regulating cell behavior, structure and fate.

Acknowledgments

Research conducted in our laboratory on the molecular diversity of integrin adhesions was supported by the Israel Science Foundation and by the Henry Kreuter Foundation. Benjamin Geiger is the incumbent of the Erwin Neter Professorial Chair in Cell and Tumor Biology.

Cell Migration

Introduction

Cell migration is a fundamental process throughout evolution. Some prokaryotic cells are able to swim in fluid media using specialized structures, for example, flagellae, to propel the cell body directionally, or move using different strategies, for example, sliding, gliding, etc. These movements aim to establish new colonies away from the original or search for nutrients.

Unicellular eukaryotic cells, for example, amoebae, undergo chemotaxis while searching for food. In higher organisms, for example, mammals, different cell types display various modes of migration while responding to varied extracellular stimuli. Migration is crucial in tissue morphogenesis, regeneration, or inflammation. Alterations of the migratory patterns of specific cell types, for example, leukocytes, underlie disease, for example, autoimmune disease. Migration is also an important component of the pathogenesis of cancer during invasion and metastasis. Conversely, lack of migration is a major cause of failure of potential regenerative therapies, for example, using stem cells.

Cell migration requires the integration of complex cellular responses responding to multiple signals. It is now a fully formed field that encompasses almost 40 years of research. In this article, we provide an outline of eukaryotic cell migration; its fundamental modes and underlying subprocesses; molecular effectors and regulators; and roles in homeostasis and disease.

Alone or in the Company of Others: Modes of Eukaryotic Cell Migration

Eukaryotic cells display different migratory modes depending on their intrinsic nature or microenvironment. We classify migration into two major categories, single-cell and multicellular (Friedl and Wolf, 2010). Single-cell migration is typical of highly differentiated cells with specific functions, for example, leukocytes or neuronal progenitors; collective migration refers to the simultaneous and coordinated migration of multiple cells while in contact with others. This is typical of monolayers with structural/support roles, for example, fibroblasts or epithelial cells.

Single-cell migration is further subdivided according to the morphology of the cell: most constitutively adherent cells, for example, fibroblasts, neuroblasts, etc., display mesenchymal cell migration, characterized by low speed, high adherence, extension of large protrusions and reorganization, and/or degradation of the extracellular matrix (ECM) (Ridley *et al.*, 2003). Leukocytes display amoeboid migration, in which cells are faster, less adherent, display smaller protrusions, and are much less contractile (Lammermann and Sixt, 2009). Some cells display bleb-based motion, in which cells move slowly by extending membrane blebs and do not require receptor-mediated adhesion (Charras *et al.*, 2008; Figure 1(a)).

Multicellular migration comprises chain migration, which displays leader cells at the forward edge and trailing cells behind those. This is typical of neural crest cells (Theveneau and Mayor, 2012). Collective migration occurs when multiple cells form a coordinated front that moves in unison, with layers of trailing cells following them: this occurs during early embryogenesis and wound healing (Shaw and Martin, 2009; Figure 1(b)).

Most cells exhibit a degree of 'migratory plasticity' that enables them to switch back and forth between migratory modes. For example, mesenchymal cells may undergo amoeboid or bleb-based migration under specific adhesive conditions (Chen *et al.*, 2012; Bergert *et al.*, 2012), particularly during malignant transformation (Sanz-Moreno *et al.*, 2008). These changes reflect the adaptability to the microenvironment and dynamic nature of the migratory process.

Individual Cell Migration

Mesenchymal migration

This type of cellular movement is characterized by strong adhesion and front-back cell polarization driven by actin (Figure 2(a)). Mesenchymal cells, for example, fibroblasts, develop a leading edge in the direction of migration, which appears as a forward deformation of the plasma membrane, or protrusion. Protrusion is driven by actin polymerization (Pollard and Borisy, 2003) and is enabled by adhesion to the substrate (Choi *et al.*, 2008). This is a process that is dependent on integrin receptors (Hynes, 2002), which form extended interactive signaling networks that coordinately control actin polymerization and adhesion (Aguilar-Cuenca *et al.*, 2014). In most mesenchymal cells, protrusions contain two major regions based on the conformation of the actin cytoskeleton as well as the shape and dynamics of the adhesive structures that they contain. The lamellipodium is closer to the leading edge and is formed by newly polymerized, branched actin (Svitkina and Borisy, 1999). In most cells, it is $\approx 1 \mu\text{m}$ wide. Width is relatively stable due to actin treadmilling, in which the lamellipodium grows at the outer edge due to actin monomer incorporation to the actin barbed ends closer to the edge and disassembles at its rear due to actin depolymerization. Adhesions in the lamellipodium are short lived and small (Alexandrova *et al.*, 2008; Choi *et al.*, 2008). The $\approx 5\text{--}10 \mu\text{m}$ behind the lamellipodium are commonly referred to as the lamellum. Actin reorganizes into larger bundles of filaments due to the action of actin cross-linking proteins, for example, non-muscle myosin II (NMII). Adhesions become larger and more stable. The function of the lamellum is likely to isolate cellular structures from the rapid retrograde flow of the actin at the lamellipodium while connecting this subdomain to the rest of the cell body (Verkhovsky *et al.*, 1999).

Increased adhesion size in the lamellum results from the process of adhesion maturation, which occurs along actin

Figure 1 Modes of eukaryotic cell migration. (A) Types of individual cell migration. (a) Mesenchymal migrating cell, the cell is polarized and it rearranges the ECM (shown as densely packed black strands at one pole of the cell) as it migrates. (b) Amoeboid, the cell is also polarized but it is less contractile, reorganizes the ECM (depicted as loosely organized strands) to a much lower extent and shows less interaction with the ECM. The cell also is polarized, however are much less contractile. (c) Blebbing motility. Hydrostatic pressure generates a bleb on one side of the cell, but the overall morphology is not polarized. (B) Types of multicellular migration (a) Chain migration, a leader cell drives migration of a chain of follower cells bound to each other head to tail. The leading cell is polarized (b) Collective migration. A layer of cells invades a tissue gap led by a row of protruding cells (protrusion is represented as a discontinuous line along the leading edge of the first row of cells). Movement may occur on one side only or on both sides (as depicted). In all images, arrows point to the direction of migration.

templates (bundles) that form due to actin cross-linking (Choi *et al.*, 2008). The precursors of the lamellar adhesions are dynamic nascent adhesions generated in the lamellipodium that remain behind but do not disassemble as the lamellipodium moves forward. The frequency of adhesion maturation depends on the cell type and its microenvironment, and is controlled by the stability and length of the actin templates that guide their elongation (Choi *et al.*, 2008). These adhesions likely generate tension to drive forward the cell body.

The trailing edge of these cells undergoes constant adhesion disassembly driven by tension as well as proteolysis of adhesion proteins within focal adhesions.

Different lines of evidence indicate that single mesenchymal cells form the rear first, i.e., protrude away from a non-dynamic area that becomes the rear as the cell polarize. This region is dependent on early assembly of NMII, which acts as an anti-protrusive factor that shuts down the prospective trailing edge of the cell as it spreads (Vicente-Manzanares *et al.*, 2011).

A likely similar mechanism takes place in collective chain migration, in which the tail of the leader cell shuts down the leading edge of the followers, promoting cadherin-based cell–cell adhesion instead.

Amoeboid migration

Amoeboid motion is typical of some protozoa and leukocytes. **Figure 2(b)** shows that, in 2-D, leukocytes require integrins for migration, but adhesion is not as strong as in mesenchymal cells. Several authors have indicated that in 3-D, integrin-mediated adhesion may be dispensable (Friedl and Weigelin, 2008; Lammermann *et al.*, 2008). Weaker adhesion is on display in the nature of the adhesive structures, which very seldom reach the size and stability of those observed in fibroblasts (Chen *et al.*, 2012). Amoeboid cells sustain high migratory speeds, which can be 10-fold higher than that of mesenchymal cells ($> 10 \mu\text{m min}^{-1}$ compared to $0.2\text{--}2 \mu\text{m min}^{-1}$ in fibroblasts). Some principles of mesenchymal migration apply, i.e., formation of a protrusive leading edge that contains small, dynamic adhesions. The lamellipodium is similar to that observed in mesenchymal cells, but the lamellum is poorly defined and contains no large adhesions. The trailing edge of these cells is very contractile and pushes the nucleus forward, in some cases to squeeze it through confined spaces, for example, during leukocyte extravasation (Jacobelli *et al.*, 2013). Amoeboid cells are more agile than mesenchymal cells to migrate in response to microenvironment changes. An example is the ability of cells to turn in response to an orientation change of an extracellular chemoattractant. Mesenchymal cells make a new leading edge in the new direction of the gradient, retract the old leading edge, and repolarize. Conversely, amoeboid cells turn, repositioning their existing leading edge in the new direction (Kwon *et al.*, 2013). This may be important for the ability of leukocytes to chase pathogens or migrate rapidly in response to sudden microenvironment changes, for example, during inflammation.

Blebbing motion

Blebbing motility does not require actin polymerization for membrane extension. This is due to variations in hydrostatic pressure within the cell. Blebs are membrane ‘bubbles’ that emerge in the cellular periphery. Blebs form when the actomyosin cortex that underlies the plasma membrane separates from the phospholipid bilayer by contraction or disassembly. The newly formed space fills rapidly with cytoplasm, which increases the volume locally and expands the plasma membrane. In most cases, the underlying actin cortex is reformed by mechanisms unknown (the most common actin nucleators, i.e., actin-related protein 2/3 (Arp2/3) or formins, have not

been found in these regions) (Charras *et al.*, 2008). Finally, bleb retraction requires recruitment of NMII to the bleb to support inward contraction.

Membrane blebbing is mostly used for migration in 3-D environment. In this context, cells squeeze the blebs into narrow gaps and undergoes forward motion by using the bleb to cling to the sides of the gap, using them as footholds (Renkawitz and Sixt, 2010; **Figure 2(c)**).

Multicellular Migration

Chain migration

In this migratory mode, a leader cell drives forward migration in a similar manner to that described for mesenchymal cells. The trailing edge of this cell remains adhered to a follower cell using cadherin receptors; this cell may drag another cell and so forth, forming ‘Mexican trains.’ This is characteristic of neuroblast migration, which occurs along glial patterns (Solecki *et al.*, 2009). Sahai and coworkers also described how skin fibroblasts lead squamous cell carcinoma cells (SCC) as they invade the surrounding tissue in a radial manner (Gaggioli *et al.*, 2007).

Collective migration

This is typical of regenerative processes, for example, wound healing, and in development. A row of leader cells (which contact each other side to side) moves coordinately forward, followed by a cellular monolayer. Only cells from the leading row display protrusive leading edges. Follower cells have no leading edges; instead, they remain attached to the leading row and among themselves via cell–cell adhesion receptors. Posterior cells move using actomyosin contractility and are pushed forward by proliferation.

Building a Migrating Cell

A multitude of extracellular and intracellular molecules control the dominant migratory mode of a cell, or even whether it migrates or not. In the following sections, we outline most of these factors, from the outside to the inside of the cell, and their major roles in cell migration.

Extracellular Factors

ECM

ECM provides most of the adhesive backbone for cells to migrate. ECM proteins include collagens, fibronectin, laminin, vitronectin, and many others. Most of them support adhesion

Figure 2 Features of individually migrating cells. (a) Mesenchymal migration. Figure represents a top and side view of a migrating mesenchymal cell. Close to the leading edge, the lamellipodium displays branched actin (right insert) and small, nascent adhesions (in yellow). The lamellum connects the lamellipodium to the cell body. Actin switches from branched to bundled and adhesions become elongated along actin bundles (yellow ellipses on thick red lines). In the cell body and trailing edge, adhesions are big and actin bundles are thick and long (left insert). Adhesions act as focal points for ECM reorganization (black strands). The MTOC (green) localizes in front of the nucleus (blue). (b) Amoeboid migration. The cell depicted is polarized and displays a thick lamellipodium (red band on right) decorated with small adhesions (yellow dots). The lamellum is not apparent and the nucleus appears forward, leaving the MTOC behind (green). The trailing edge is very contractile and pushes the nucleus to leading edge. (c) Migration by blebs, an initial disassembly of the actin cortex (1) induces a local increase in hydrostatic pressure (represented as a color gradient toward the right), promoting membrane deformation and sprouting of a membrane bleb (2–3). Actin reforms into the bleb, stabilizing the structure (4) and enabling its use as an anchor point on the ECM (represented with black arrows).

via one, or several, integrin-type receptors. ECM proteins (and some cellular integrin ligands) display specific epitopes, for example, the RGD (Arg-Gly-Asp) sequence, which support integrin binding. ECM proteins are major constituents of the extracellular milieu in solid tissues and form elastic bundles (e.g., collagen) that cells use as migratory tracks. At the same time, migrating and contracting cells, particularly mesenchymal, constantly remodel the ECM fibers (e.g., during wound healing). Migrating amoeboid or bleb-based cells reorganize the ECM to a much lower extent.

Some cellular transmembrane proteins also display integrin-binding ability (they contain RGD or RGD-like motifs). Most belong to the Ig-like cell adhesion molecule family, for example, intercellular cell adhesion molecules (ICAMs), vascular cell adhesion molecule (VCAM), neural cell adhesion molecule (NCAM), etc.

Cell adhesion depends on ECM concentration following a saturable curve. Conversely, cell migration depends on the concentration of ECM in a biphasic manner. This means that, for each cell type, an optimal concentration of substrate best supports migration; under that threshold, cells do not grip sufficiently and cannot move; over the threshold, cells are too adhesive and remain attached (Polecek *et al.*, 1997).

Soluble chemoattractants

Several families of cytokines and growth factors are chemotactic, i.e., attract migrating cells. Chemotaxis triggers cellular protrusion in the direction of maximal concentration of a soluble gradient of the chemoattractant. Chemoattractants comprise several large groups. Chemokines are a large (>40) family of potent chemoattractants for leukocytes and other cell types that act through G protein-coupled receptors (GPCR). Some bacterial peptides, for example, formyl-Met-Leu-Pro (fMLP), and small subunits of complement, for example, C5a, also behave as chemoattractants through GPCR. Another family includes those GF that interact with Tyr kinase receptors, for example, insulin, vascular endothelial growth factor (VEGF), or ephrins. Most of these are chemotactic for cells that migrate in a mesenchymal manner, for example, fibroblasts, endothelial cells, or neuron progenitors.

Mechanical forces

Cells generate and respond to mechanical forces as they migrate. Through adhesions, cells generate traction forces on the ECM to promote tissue remodeling (Legant *et al.*, 2012). Likewise, forces imposed on migrating cells modulate their response. Cells not only react to vector forces and pressure (force per area), but they also modulate their migration by sensing the mechanical properties of their microenvironment. Durotaxis is the property by which cells migrate better on stiff than soft substrates and, given the choice, migrate toward stiffer substrates (Raab *et al.*, 2012).

Membrane Receptors

Integrins and focal adhesion proteins

Integrins are heterodimeric proteins that function as adhesion receptors (Hynes, 2002). To understand their role in cell migration, we will focus on two major properties: the

regulation of their activation and their ability to connect the ECM to the cellular cytoskeleton. According to their activation, there are two major classes of integrins: those that display constitutive activation, for example, fibroblast integrins; and those activated in response to stimulation, for example, those expressed in platelets and leukocytes. Their affinity increases in response to ligand exposure but also requires inside-out signals: activation of the T-cell receptor, GPCR, Tyr kinase GF receptors, etc., promotes integrin association to the actin cytoskeleton through an array of adaptors, referred to as adhesion proteins or the 'adhesome' (Zaidel-Bar *et al.*, 2007). These behave as a molecular clutch that modulates the extent of integrin activation and adhesion as well as migration (Aguilar-Cuenca *et al.*, 2014). Integrins also display regulated avidity, i.e., their ability to form plasma membrane aggregates (Carman and Springer, 2003). Adhesion proteins also regulate integrin avidity by forming interactive platforms through their association to actin.

A few notable adhesion proteins include talin, which links the cytoplasmic domain of the β chain of the integrin with actin. Talin is directly responsible for the conformational extension of the integrin in response to inside-out signaling by inducing an integrin conformational change that renders it ligand binding-competent. Vinculin is an adaptor protein that binds talin and actin and reinforces adhesion protein clustering (Bakolitsa *et al.*, 2004; Dumbauld *et al.*, 2013). Focal adhesion kinase (FAK) is a Tyr kinase that phosphorylates several substrates, most notably Src, in response to integrin activation and amplifies adhesive signals (Parsons, 2003). Paxillin is another scaffold protein that is heavily phosphorylated in response to adhesion and has multiple partners, being one of the best characterized adaptors in adhesive signaling (Deakin and Turner, 2008). A large interactive network for adhesion proteins underneath integrins has been published recently (Zaidel-Bar *et al.*, 2007; Figure 3).

Chemoattractant receptors

Most chemoattractant receptors belong to the GPCR family of seven transmembrane domains. These receptors are phosphorylated and internalized in response to ligand binding by a GRK- β -arrestin-dependent mechanism (Luttrell and Lefkowitz, 2002). G protein activation initiates a signaling cascade that includes cAMP and PIP₂ synthesis and activation of the Ras/PI 3-kinase pathway (McCudden *et al.*, 2005). They also promote actin polymerization dependent of Rac (see Section Actin polymerization (lamellipodium)) to generate protrusion in the direction of higher concentration of the gradient (Van Haastert and Devreotes, 2004). Localized protrusion occurs because cells are able to perceive small ($\leq 2\%$) differences in the concentration of the chemoattractant, and polarize the signaling intermediates toward the higher concentration of activated receptors (Iglesias and Devreotes, 2008; Figure 4).

Tyr kinase receptors usually have one transmembrane domain and contain a kinase domain in their C-terminus that usually undergoes autophosphorylation. Receptor autophosphorylation recruits other kinases, for example, Src, which trigger signaling cascades that also induce actin polymerization to form protrusions (Endres *et al.*, 2011).

Figure 3 Integrin transactivation by GPCR. In addition to the canonical Gi-dependent and GRK-arrestin internalization pathways, chemoattractant binding to specific GPCR (left, shown in purple) activates the small GTPase Rap (yellow) and its effector RapL (orange), which promote integrin transactivation via kindlins. GPCR also transactivate integrins by promoting talin extension and association to the β chain of the integrin and inducing a conformational change to the integrin that triggers integrin binding to its ligands (ECM) formation of adhesive complexes to ligand-bound integrins. Some adhesion proteins are shown, including vinculin, FAK, and paxillin.

Intracellular Determinants

Actin filaments

Actin is the fundamental cytoskeletal molecule that regulates cell migration. Actin polymerization underlies protrusion formation, adhesion generation, and stabilization/turnover. Stable actin provides cortical integrity and the balance between dynamic, stable, and monomeric actin controls multiple phenomena, from migratory polarization to retraction of the rear, etc. In migrating cells, actin appears in two major forms: polymerized and monomeric. Many studies and reviews have covered the subject (Campellone and Welch, 2010; Pollard and Borisov, 2003).

Polymerized actin appears in different conformations, from densely packed branched thin filaments in lamellipodia (Svitkina and Borisy, 1999) to large and contractile actin bundles in the sides and rear of mesenchymal cells (Cramer *et al.*, 1997). Other migratory structures are podosomes and invadopodia, which are actin-rich rings that support cell migration and spatially confine metalloprotease secretion (Linder and Kopp, 2005). Actin also forms a subcortical network that controls the hydrostatic pressure of the cytoplasm as well as its integrity (see blebbing motility, see Section Blebbing motion). Each of these structures displays different architectures and assembly dynamics. This is due to the different actin-binding proteins in each structure as well as the mechanical properties of the subcellular region in which they each appear. In the lamellipodium, the actin mostly adopts a branched conformation due to the activity of the Arp2/3 complex. The Arp2/3 complex is an actin nucleator that binds to the side of an existing actin filament and generates a new

barbed end forming an angle of approximately 70° with the mother filament. At the tip of the lamellipodium, formins, for example, Diaphanous proteins, nucleate actin monomer incorporation to the barbed ends in a processive manner (Campellone and Welch, 2010). At the base of the lamellipodium, cofilin and normal filament aging disassemble actin filaments (Pollard and Borisy, 2003).

Actin dynamics direct adhesion formation and disassembly. Adhesions are linked to actin and disassemble in its absence. Likewise, adhesion elongation is driven by actin bundling in the lamellum. In areas of dendritic actin, actin cross-linkers are not abundant (Zaidel-Bar *et al.*, 2003). Conversely, NMII and α -actinin are both found in the lamellum and promote the actin assembly into larger bundles. Actin bundling also regulates cortical integrity and membrane coherence (Choi *et al.*, 2008; Cai *et al.*, 2010).

Microtubules

The role of microtubules in cell migration has been the focus of recent reviews (Etienne-Manneville, 2013; Kaverina and Straube, 2011). Migrating mesenchymal cells devoid of microtubules disconnect the front from the rear and lose cellular coherence (Verkhovsky *et al.*, 1999; Vicente-Manzanares *et al.*, 2011). However, amoeboid cells migrate almost normally (Ratner *et al.*, 1997). Microtubules and microtubule-associated proteins also control the relative positioning of the microtubule-organizing center (MTOC) and the nucleus during mesenchymal cell migration (Gomes *et al.*, 2005) and target adhesions to promote their disassembly (Kaverina *et al.*, 1999).

Figure 4 Cellular response to a uniform chemoattractant gradient. Top row, cells display initial signaling quiescence (shown as thin blue line) when it does not perceive the gradient. Middle row, polarized activation (depicted as thick blue line) of the signaling upon gradient sensing on one side of the cell (right side). Bottom row, polarized signaling promotes localized actin polymerization, making a leading edge in the direction of the gradient.

Regulation and integration

In this section, we overview several well-defined regulatory pathways involved in the generation of different migratory cellular structures. For more details, see [Vicente-Manzanares et al. \(2005\)](#).

Actin polymerization (lamellipodium)

Actin polymerization is controlled by small Rho GTPases (mainly RhoA and Rac1). Integrins cluster and activate Rho activators (GEFs) in nascent adhesions ([Kuo et al., 2011](#)), while chemoattractant receptors activate GEFs at the leading edge of the plasma membrane ([Iglesias and Devreotes, 2012](#)). Initially, RhoA activates formins at the very leading edge to drive actin polymerization at the barbed ends closer to the plasma membrane; immediately afterwards, Rac1 activation drive local nucleation of actin

filaments in the lamellipodium via Arp2/3 ([Machacek et al., 2009](#); [Figure 5](#)).

Actin reorganization (lamellum)

As adhesions grow, Rac1 signaling subsides and RhoA signaling becomes predominant ([Machacek et al., 2009](#)). In this area RhoA acts through the Ser/Thr kinase Rho-associated protein kinase (ROCK) to promote NMII recruitment and activation ([Totsukawa et al., 2004](#)). NMII and other nonmotor actin cross-linkers induce actin filament coalescence into bundles. In turn, actin bundling increases adhesion stabilization ([Vicente-Manzanares et al., 2011](#)).

Front-back polarity

Different molecular mechanisms, for example, microtubules and the Cdc42/aPKC/Par3/6 complex coordinately control

Figure 5 Actin organization at the leading edge. Image depicts a representation of the major pathways of actin organization downstream of chemoattractant and integrin receptors. GPCR or Tyr kinase-type receptors (GF-R) trigger activation of small GTPases and actin polymerization. RhoA (yellow) is activated in the lamellipodium and triggers actin polymerization at the barbed end (+) via formins. These receptors also activate Arp2/3 via Rac1 and promote actin branching at a fixed angle (dotted lines). During lamellipodial formation, actin polymerization guides nascent adhesion formation and integrins also activate the same GTPases. At the lamellum, signaling promotes myosin II activation via RhoA/ROCK, which in turn induces actin bundling and adhesion maturation.

nuclear localization and the relative position of the front and rear in response to migratory cues (Gundersen and Worman, 2013).

Rear detachment

Three mechanisms have been postulated: NMII retraction (Chrzanowska-Wodnicka and Burridge, 1996), proteolytic activation (Huttenlocher *et al.*, 1997), and integrin endocytosis, probably dependent of microtubules (Ezratty *et al.*, 2009; Kaverina *et al.*, 1999).

Migration in Development and Homeostasis

Migratory events underlie embryo and organ development. It also maintains homeostasis of the adult and participates in normal regeneration as well in the immune response.

Embryonic Development

During gastrulation, the cells that form the prospective mesoderm and endoderm invade the ectoderm to form the three primordial layers. This is a process of collective migration in chains, in which prospective mesoderm cells constitute the leading edge of the chain toward the animal pole of the embryo (Keller, 2005). Directional guidance of these chains involves haptotactic (immobilized/adherent) and chemotactic (soluble) cues, including platelet-derived growth factor (PDGF) and members of the Wnt family (Nagel *et al.*, 2004). Haptotactic gradients of morphogens evolve over time and space to segregate the different cell types into their proper locations to begin differentiation. Migratory events also shape the later stages of embryonic development. For example, during dorsal closure, border cells migrate to occlude the amnioserosa (Young *et al.*, 1993). Closure requires mechanical tension at the leading edges of the layer: the edges pull side to

side to close the gap (Franke *et al.*, 2005). In muscle development, progenitors migrate into the limbs driven by hepatocyte growth factor (HGF), which is expressed gradient-wise by non-progenitor mesoderm cells. HGF binds to the c-Met receptor expressed by the progenitors (Heymann *et al.*, 1996).

Migration in the Central Nervous System

Migration is most active during formation of the Central Nervous System (CNS). Although the initial signals that form the neural plate induce differentiation of the neural plate, the segregation of the brain into its definitive compartments requires neuroblast migration, which occurs following these models:

- Tangential migration: Neuroblasts navigate in a mesenchymal manner toward their differentiation niches. They are guided by an exquisite balance of chemoattractant, chemorepellent, and adhesive signals (Nakajima, 2007). An example is the migration of neuroblasts from the sub-ventricular zone (SVZ) to the olfactory bulb (OB) (Muras and Horwitz, 2004).
- Radial migration: Initially, progenitors migrate as individual cells and extend long processes as they differentiate into radial glial cells, protruding toward the pia and contracting the cell body toward the leading edge. These cells can differentiate into mature glial cells or neurons (Fricker-Gates, 2006). Their long processes act as haptotactic/durotactic cues used by subsequent waves of individual neuroblasts to migrate to the different layers of the brain. Confinement to the processes is optimized by chemorepellent signals on the sides of the cue (Marin and Rubenstein, 2003).
- Axophilic migration: Cells use their own axons as a guidance cue to move the soma (Wray, 2010).

Inflammation

Inflammation in response to a pathogen involves two major migratory steps: emigration of the responder leukocytes from the bloodstream into the target tissue and tissue migration of the leukocytes. The former is coordinately regulated by shear stress and transmembrane receptors of different families, e.g., selectins, integrins, and chemokine receptors expressed by leukocytes that interact with endothelial ligands (Vestweber, 2012).

In tissues, leukocytes migrate in an amoeboid manner. The role of integrin-based adhesion is diminished compared to mesenchymal cells in 2-D and 3-D and amoeboid cells in 2-D. This is due to the geometry of the ECM, which displays narrow openings through which leukocytes squeeze using the sides of the gaps as footholds (Renkawitz and Sixt, 2010). For guidance, cells use gradients of immobilized chemoattractants, for example, CCL21 in skin (Weber *et al.*, 2013).

Migration in Pathology

Abnormal migratory phenomena are also cause or part of the onset of several pathologies, most notably cancer and autoimmune disease.

Cancer

Tumor cells migrate to distal sites to form secondary tumors (metastasis). They undergo egress from the primary tumor and move toward blood vessels or lymphatics. Then, they migrate to distal sites and extravasate by mimicking the process used by leukocytes, or bursting through the capillary vessels. Once within the new tissue, tumor cells migrate to explore their new microenvironment, immobilize and proliferate to generate a new tumor.

At the edges of the tumor, migration is mainly multicellular, with chains or sheets of tumor cells emerging from the primary tumor in waves. As they migrate away from the primary tumor, some of these begin migrating individually (Friedl *et al.*, 2012). The predominant migratory mode depends on the origin of the tumor. Carcinomas, which are epithelial in origin, are thought to migrate mostly in a mesenchymal manner. Conversely, leukemic cells are hematopoietic and thus migrate in an amoeboid manner. However, some tumor cells can switch between modes rapidly to adapt to the mechano-chemical properties of their microenvironment (Bergert *et al.*, 2012).

The prevalent hypothesis regarding initiation of carcinoma migration involves the conversion of epithelial-like tumor into migration-competent cells through the epithelial-mesenchymal transition (EMT). This is a genetic switch that inactivates genes that confer epithelial traits to the cells and activate genes that enable migration in a mesenchymal manner. Once motile, cells are able to switch between migrating modes in response, for example, to variations in the composition of the ECM or structural or geometrical differences (Bergert *et al.*, 2012).

This is a very active area of research since metastasis is responsible for approximately 90% of cancer-related deaths. Therefore, the ability to halt cancer cell migration becomes the focal point of potential anti-metastasis therapy (Stock *et al.*, 2013).

Angiogenesis is an additional component of the onset of cancer in which migration plays a fundamental role. Tumors secrete chemotactic molecules for endothelial precursors, for example, VEGF. Precursors then invade the tumor and form new blood vessels connected to the general bloodstream, thereby generating a source of oxygen and nutrients that feed the tumors directly. Therefore, another therapeutic opportunity is blocking endothelial cell migration to the tumor to prevent *de novo* vascularization, thereby starving the tumor (Weis and Cheresh, 2011).

Autoimmune Disease

Part of the onset of autoimmune diseases is the migration of leukocytes to sites where they recognize self-antigens as foreign and mount an immune response against them. Some examples include rheumatoid arthritis (RA), diabetes, psoriasis, multiple sclerosis (MS), Crohn's disease (CD), and some others. The etiology of these diseases is complex and includes genetic and environment factors. However, the manifestation of the disease includes self-perpetuation of the inflammatory response and leukocyte infiltration (mainly neutrophils and autorreactive T cells) that causes inflammatory damage (Wright *et al.*, 2010). CD4+ T cell migration into the tissue

promotes and sustains inflammation (Toh and Miossec, 2007); whereas migrating CD8⁺ T cells destroy tissue cells that display autorreactive epitopes, for example, Langerhans cells in diabetes (Tsai *et al.*, 2008). Anti-migratory therapy works to treat some of these diseases. For example, natalizumab is a humanized anti-CD49d ($\alpha 4$) antibody that is used to control multiple sclerosis. Its mechanism of action prevents leukocytes from migrating to the CNS (Von Andrian and Engelhardt, 2003). Another example is efalizumab, which targets CD11a (αL) and has been used to treat psoriasis by preventing T cell and neutrophil migration to the injured skin (Frampton and Plosker, 2009).

Harnessing Cell Migration in Therapy

As described in the previous section, inadequate migration can cause severe disease. Conversely, there are instances in which the lack of migration prevents therapy. For example, in spinal cord injury, lack of neuroblast migration to the site of injury is a major reason for regenerative failure. A similar reason prevents myocardial regeneration upon congestive heart failure and necrosis. Most stem cell based approaches fail due to the inability of these cells to position correctly within the injured tissue prior to undergoing differentiation into target cells.

Several reasons concur to cause migratory failure. For example, damaged or scarred tissue does not provide an adequate microenvironment to stimulate and support stem cell migration. Additional reasons include physical resistance due to fibrosis and residual inflammation that can kill the regenerating cells. Future research will address these issues to be able to promote controlled cell migration in these hostile environments to support efficient regenerative therapies.

Conclusions

- Cell migration is a fundamental process in physiology and pathology that requires the interaction of many proteins and cell structures in response to extracellular and intracellular signals.
- Eukaryotic cells display different migratory modes: Single-cell migration is typical of highly differentiated cells and collective migration refers to the simultaneous and coordinated migration of multiple cells while in contact with others.
- Single-cell migration can be mesenchymal or amoeboid. Mesenchymal movement is slow and features strong adhesion to the ECM and complex cytoskeletal structures and produces tissue remodeling. Amoeboid migration is faster, with weak adhesion and modest perturbation to tissue morphology.
- Migratory processes are crucial in embryo and organ development. In later stages, it maintains tissue homeostasis and participates in normal regeneration as well as in the immune response.
- Abnormal migratory phenomena are cause or part of the onset of several pathologies, most notably cancer and autoimmune disease.

Rho GTPases

MJ Lukey and RA Cerione, Cornell University, Ithaca, NY, USA

© 2016 Elsevier Inc. All rights reserved.

General Features

There appear to be at least 20 members of the Rho GTPase family in mammals, based on genome sequence analyses (Jaffe and Hall, 2005; Boureux *et al.*, 2007). Rac, Rho, and Cdc42 each have more than one form (e.g., Rac1, Rac2, RhoA, RhoC etc.) and are found in virtually all animals. Cdc42 is rigorously conserved from yeast to humans, which suggested that it along with its close cousins were likely to play fundamentally important roles in cell biology. Indeed, their requirement for the maintenance of cell shape, polarity, and for the necessary actin cytoskeletal changes supporting these processes, is consistent with this assumption. Like the Ras GTPases, members of the Rho subfamily undergo a tightly regulated exchange of GDP for GTP in order to mediate their specific signaling activities. Moreover, similar to the Ras GTPases, the Rho proteins make use of conformationally sensitive regions, referred to as Switch 1 and 2, to trigger their signaling events, as well as a regulated GTP-hydrolytic activity to switch off their signal outputs.

Nonetheless, the Rho GTPases have a number of important features that distinguish them from their Ras GTPase counterparts. One of these involves the posttranslational modifications that occur within the carboxyl terminal CAAX box, and which are essential for membrane association. While the Ras GTPases contain a farnesyl moiety at their CAAX box, as well as in some cases (H- and N-Ras) a palmitoyl group at a cysteine located 4 residues upstream from the cysteine that starts the CAAX motif, the Rho GTPases typically contain a geranyl-geranyl moiety at their CAAX box cysteine residue (Michaelson *et al.*, 2001). One exception is the brain-specific isoform of Cdc42, which has a double cysteine motif within its CCAX carboxyl terminal and has been suggested to undergo a combination of geranyl-geranylation, palmitoylation, and farnesylation modifications (Kang *et al.*, 2008).

A second distinction between the Ras and Rho proteins is that a significant fraction of the Rho GTPases is typically found in the cytosol. This cytosolic localization is due to the actions of a family of regulators collectively called RhoGDI (for Rho GDP-dissociation inhibitor). Yoshimi Takai, who together with his colleagues was largely responsible for showing that the Ras proteins were the prototypes for a large superfamily of small GTPases (originally called Smgs for small molecular weight GTPases) (Takai *et al.*, 1988), was the first to identify two classes of regulatory proteins named GDI that slowed GDP dissociation from the Rab and Rho GTPases (thus called the Rab and RhoGDIs, respectively) (Sasaki *et al.*, 1990; Ueda *et al.*, 1990; Fukumoto *et al.*, 1990). The GDIs also were capable of facilitating the membrane-to-cytosolic transition of the Rab and Rho proteins (Leonard *et al.*, 1992). The RhoGDIs include RhoGDI α (or RhoGDI1), the hematopoietic-specific RhoGDI β (RhoGDI2), and RhoGDI γ (RhoGDI3). The X-ray crystal structure for GDP-bound Cdc42 complexed to RhoGDI demonstrated how the geranyl-geranyl moiety of Cdc42 fits

into a hydrophobic pocket within the GDI molecule (Hoffman *et al.*, 2000). More recently, new insights were obtained into the mechanism by which RhoGDI plays one of its most important roles, namely, in stabilizing the soluble, cytosolic state of Cdc42 (Johnson *et al.*, 2009). Contrary to what was originally assumed, RhoGDI does not appear to actively extract Cdc42 from membranes. Rather, the membrane association of Cdc42 is a dynamic process, i.e., it associates and dissociates from membranes with measurable rates. RhoGDI binds Cdc42 while it is associated with membranes. Surprisingly, it was shown that the RhoGDI-Cdc42 complex dissociates from membranes with a rate that matches (and does not greatly exceed) that for the dissociation of Cdc42 from membranes in the absence of RhoGDI. Once the RhoGDI-Cdc42 complex has dissociated from membranes, RhoGDI can sequester the geranyl-geranyl moiety of Cdc42 and help stabilize the GTPase in the cytosol until the appropriate time for Cdc42 to engage its upstream activators or downstream signaling targets.

Regulation of the GTP-Binding/GTP-Hydrolytic Cycles of Rho GTPases

As is the case for the Ras proteins, the GTP-binding and GTP-hydrolytic activities of the Rho GTPases are tightly regulated by the combined actions of guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs) (Figure 1). The founding member of an important superfamily of GEFs is the product of the *DBL* oncogene (Eva and Aaronson, 1985; Hart *et al.*, 1991). Proto-Dbl is an 115 kDa protein, whereas oncogenic Dbl was generated as an outcome of a recombination event when transfecting DNA from a diffuse B-cell lymphoma into fibroblasts. The amino-terminal half of proto-Dbl was removed and replaced by ~10 kDa of unrelated human sequence, yielding the 66 kDa oncogenic Dbl protein. Studies with the recombinant oncogenic Dbl protein showed that the limit region required for GEF activity was within a stretch of ~250 amino acids, subsequently termed the Dbl homology (DH) domain, which is conserved throughout a number of other proteins that would turn out to be Rho GEFs (Hart *et al.*, 1994). Immediately downstream from this region is another conserved stretch of sequence, now known as the Pleckstrin-homology (PH) domain. This tandem arrangement of DH and PH domains would become a characteristic feature of the Dbl-family of Rho GEFs, which includes the *Saccharomyces cerevisiae* Cdc24 protein, the Vav oncogene product which was first identified in hematopoietic tumors, the highly specific Rac-GEF Tiam-1 which was discovered when screening for gene products linked to metastasis, the Cool/Pix proteins, and p115RhoGEF which contains an RGS (regulator of G protein signaling) domain and couples the large G protein G₁₃ to the activation of RhoA (Figures 2(a) and 2(b); Cerione and Zheng, 1996; Rossman *et al.*, 2005). The fact that many of

Figure 1 The Rho GTPase cycle. Rho GTPases are inactive when bound to GDP, and are sequestered in the cytoplasm by guanine nucleotide dissociation inhibitors (GDIs). Guanine nucleotide exchange factors (GEFs) stimulate exchange of GDP for GTP, activating the GTPase. When active, Rho GTPases interact with and activate numerous downstream effectors. GTPase-activating proteins (GAPs) stimulate the intrinsic GTPase activity, which generates GDP and inorganic phosphate (Pi), and restores the inactive state.

Figure 2 Diagram of DH domain-containing proteins. (a) Schematic diagram of the DH-PH module is shown. (b) The domain architectures of a number of Dbl-family proteins are shown.

these GEFs have been linked to cellular transformation or uncontrolled cell growth, starting with the initial discovery of oncogenic Dbl, represented the first significant clues that Rho

GTPases were involved in mitogenic signaling and cancer progression (see below). Insight into the mechanisms underlying the GEF activity of Dbl-family proteins was obtained

from the X-ray crystal structure of Rac1 in complex with the DH and PH domains of Tiam1 (Worthylake *et al.*, 2000).

A second class of GEFs for Cdc42 and Rac, that lack tandem DH and PH domains, has also been identified and characterized. This is called the DOCK180 (for Director of cytokinesis 180) family, named for its founding member (Cote and Vuori, 2002). The GEFs comprising this family are ~200 kDa in size and contain conserved domains called DHR1 and DHR2 (for DOCK homology regions 1 and 2). Many members of the DOCK180 family have been shown to activate Rac to regulate cell adhesion, cell migration, and phagocytosis. Some members of the family are specific GEFs for Cdc42, including DOCK9 (also known as Zizimin) and DOCK11 (also known as ACG for activated Cdc42-associated GEF), while others like DOCK7 are effective at activating both Rac and Cdc42 (Meller *et al.*, 2002).

The RhoGAPs also make up a large family of regulatory proteins. The founding member was an ~50 kDa protein, originally called p50RhoGAP, although it is also referred to as Cdc42GAP as it is much more effective at stimulating the GTP-hydrolytic activity of Cdc42 than of RhoA (Lancaster *et al.*, 1994). The members of this family share three regions of similarity spanning ~200 amino acids, referred to as the RhoGAP homology domain, and include the DLC1 and DLC2 proteins (for Deleted in liver cancer 1 and 2) which function as putative tumor suppressors, as well as the breakpoint cluster region (Bcr) protein which interestingly also contains tandem DH and PH domains, the 85 kDa regulatory subunit of the PI-3 kinase, and the RasGAP-binding protein p190 (Tcherkezian and Lamarche-Vane, 2007). Thus, like the Dbl-family of GEFs, a number of the RhoGAP family members have been implicated in different aspects of cell growth control and cancer, thereby providing additional links between the Rho GTPases and the transformed state. X-ray crystallographic analysis of Cdc42 bound to the Cdc42GAP shows that RhoGAPs catalyze GTP hydrolysis through a similar mechanism to that used by RasGAPs (Nassar *et al.*, 1998).

Rho GTPases and Their Roles in Regulating the Actin Cytoskeleton

Dynamic regulation of the actin cytoskeleton is required for many cellular processes, including changes in cell shape, cell migration, and cytokinesis. The results from microinjection experiments provided the first indication that the Rho GTPases are involved in controlling cytoskeletal organization. In a set of landmark publications, Ridley and Hall (1992) demonstrated that RhoA stimulated actin stress fiber and focal adhesion formation when microinjected into Swiss 3T3 fibroblasts. A number of different growth factors including PDGF, EGF, and bombesin stimulated actin reorganization and triggered a rapid formation of membrane ruffles, which was subsequently accompanied by the formation of stress fibers. Growth factor-stimulated focal adhesion assembly and actin stress fiber formation were blocked when endogenous RhoA function was inhibited by ADP ribosylation of the RhoA protein by the exoenzyme C3 transferase from *Clostridium botulinum*. Ridley, Hall and their colleagues also showed that the microinjection of Rac1 into confluent serum-starved Swiss

3T3 fibroblasts stimulated actin filament accumulation at the plasma membrane, resulting in the formation of lamellipodia (broad actin-based projections at the leading edge of motile cells) or membrane ruffles (Ridley *et al.*, 1992). Various growth factors and activated H-Ras were also shown to induce membrane ruffling with this response being blocked by the injection of a dominant-negative Rac mutant, which binds tightly to endogenous Rac-GEFs but cannot undergo guanine nucleotide exchange.

The likelihood that Cdc42 would similarly impact the cytoskeletal architecture seemed evident from its original discovery in *S. cerevisiae* by Johnson and Pringle (1990), where it was implicated in the establishment of cell polarity and the proper localization of budding sites. The human homolog was discovered based on its apparent involvement in EGF receptor signaling (Hart *et al.*, 1990). Remarkably, the cloning of the cDNAs encoding the yeast and human proteins, both reported in 1990 (Johnson and Pringle, 1990; Shinjo *et al.*, 1990; Munemitsu *et al.*, 1990), showed that they were more than 90% identical in amino acid sequence. This extraordinary conservation from yeast to humans foretold that Cdc42 would play fundamentally important roles in cell biology. Subsequently, it was shown that microinjection of activated Cdc42 mutants into Swiss 3T3 fibroblasts stimulated the formation of filopodia (slender actin-based projections that extend beyond the leading edge of lamellipodia) and microspikes (Nobes and Hall, 1995), and that at least in this cellular context, there is a GTPase cascade (Cdc42 to Rac to RhoA) that induces a specific sequence of cytoskeletal alterations (Figure 3).

The Rho GTPases regulate the actin cytoskeleton through several effector proteins (Figure 4), which together coordinate actin polymerization, branching, and actomyosin contractibility (Sit and Manser, 2011). Activated Cdc42 and Rac1 promote filamentous actin (F-actin) branching by indirectly activating the actin-related protein (ARP)2/3 complex (Jaffe and Hall, 2005). Once activated, the ARP2/3 complex binds to preexisting F-actin and nucleates the growth of branching daughter filaments, which can push forward the leading edge of motile cells (Pollard, 2007). Cdc42 signals to ARP2/3 through members of the Wiskott–Aldrich Syndrome protein (WASP) family, which, *in vitro*, are auto-inhibited by an intramolecular interaction between the C-terminal functional 'VCA' module and the N-terminal regulatory domain. Binding

Figure 3 Depiction of a Rho GTPase cascade that regulates cell shape and actin cytoskeletal organization.

Figure 4 Regulation of the actin cytoskeleton by the Rho GTPases. Rho, Rac, and Cdc42 signal through a range of kinase and non-kinase effectors to regulate aspects of the cytoskeleton. Downstream of RhoA, the diaphanous-related formin mDia catalyzes actin polymerization, and Rho-associated coiled-coil-containing protein kinase (ROCK) promotes F-actin stabilization and actomyosin assembly to generate stress fibers. Downstream of Cdc42 and Rac, the Wiskott–Aldrich Syndrome protein (WASP) family and WASP family verprolin homologous (WAVE) proteins, respectively, promote F-actin branching by activating the actin-related protein 2/3 (Arp2/3) complex, and p21-activated kinase (PAK) promotes F-actin stabilization by activating LIM kinase (LIMK), which in turn inhibits cofilin.

of activated Cdc42 to the Cdc42-Rac-interactive binding (CRIB) motif within the regulatory domain relieves this inhibitory interaction, exposing the ARP2/3 binding and activation site of WASP (Hoffman and Cerione, 2000; Bompard and Caron, 2004). Rac signals to ARP2/3 through the WASP family verprolin homologous (WAVE) proteins, which lack a GTPase-binding domain and consequently do not bind Rac directly. The three WAVE proteins (1, 2, and 3) each exist in a pentameric heterocomplex consisting of WAVE, ABI, NAP1, SRA1, and HSPC300 (Takenawa and Suetsugu, 2007). The activity of WAVE toward ARP2/3 is inhibited by intra-complex sequestration of the VCA module, and binding of activated Rac1 to Sra1 causes an allosteric release of the VCA module to activate the complex (Chen *et al.*, 2010).

A study of Rho GTPase coordination in fibroblasts found that RhoA is activated at the advancing leading edge, and Rac1 and Cdc42 are activated slightly behind the leading edge after a short delay (Machacek *et al.*, 2009). This suggests that RhoA has a primary role in leading edge protrusion, while Cdc42 and Rac1 reinforce and stabilize newly formed protrusions. Whereas Cdc42 and Rac1 stimulate F-actin branching through the ARP2/3 complex, RhoA signals through a family of proteins called formins to induce formation of straight actin

filaments. Formins are characterized by the presence of one or more formin homology (FH) domains. The diaphanous-related formin mDia1 is a direct effector of RhoA, and contains an N-terminal Rho-binding domain (RBD) within a larger autoinhibitory domain. Binding of activated RhoA to the RBD relieves an inhibitory intramolecular interaction, exposing an FH2 domain that can then bind to the barbed end of an actin filament and nucleate actin polymerization (Lammers *et al.*, 2005). mDia1 also contains a proline-rich FH1 domain, which binds monomeric profilin-bound actin and delivers it to the filament end. As the actin filament grows, mDia1 remains bound to the barbed end, recruiting further actin monomers and preventing binding of capping proteins (Zigmond *et al.*, 2003).

Rho, Rac, and Cdc42 also signal to the actin cytoskeleton through kinases such as the Rho-associated coiled-coil-containing protein kinase (ROCK) and the p21-activated kinase (PAK). When bound to activated Rho, ROCK increases myosin light chain (MLC) phosphorylation by directly phosphorylating MLC and also by phosphorylating, and inactivating, myosin phosphatase (Riento and Ridley, 2003). The result of increased MLC phosphorylation downstream of ROCK is enhanced binding of myosin to F-actin. Because myosin is

effective at cross-linking actin filaments, this enhanced binding leads to the formation of contractile actomyosin bundles known as stress fibers. In addition to promoting actomyosin assembly, ROCK signals to stabilize F-actin by phosphorylating and activating LIM kinase (LIMK). LIMK in turn phosphorylates and inactivates cofilin, an actin depolymerizing and severing factor (Riento and Ridley, 2003). The Cdc42- and Rac-activated PAK family of kinases can also signal through LIMK to inactivate cofilin (Edwards *et al.*, 1999).

Other Targets and Multiple Roles in Biology

A variety of proteins have been identified as 'downstream' targets for the different Rho family members, demonstrating that these GTPases are involved in diverse aspects of cell biology far beyond the originally identified roles in membrane ruffling and filopodia formation. For example, it was shown that Cdc42 and Rac, by directly binding and activating PAK, triggered the activation of the stress-responsive nuclear MAP kinases, c-Jun N-terminal kinase (JNK) and p38 (Jaffe and Hall, 2005). This, together with the uncovering of a similar signaling pathway in *S. cerevisiae* (Leberer *et al.*, 1997), provided the first evidence that members of the Rho GTPase family can mediate the regulation of gene expression. Similarly, RhoA was shown to signal to the serum response factor and thereby activate transcription (Jaffe and Hall, 2005).

In an elegant set of biochemical studies, the Rac2 protein (highly similar in sequence to Rac1) was shown to play an essential role in the ability of phagocytes to destroy foreign pathogens by stimulating the oxidative burst *via* the activation of the NADPH oxidase complex (Abo *et al.*, 1992; Diebold and Bokoch, 2001). Indeed, this was the first conclusive evidence that a GTP-bound Rho protein could directly engage and stimulate an effector activity. However, there probably has not been a more clear cut demonstration of the signaling flexibility of the Rho GTPases than the discovery of how Cdc42, through its engagement of a diversity of target proteins (Figure 5), impacts a wide variety of cellular functions. One rather surprising discovery was the apparent roles played by Cdc42 in intracellular trafficking events. The initial suggestions for such

a role came from immunofluorescence studies showing that a predominant cellular localization of Cdc42 was in Golgi membranes (Erickson *et al.*, 1996). This was further reinforced by experiments in which the entire COP1 coatamer complex could be affinity precipitated with GTP γ S-bound GST-Cdc42 (Wu *et al.*, 2000). Several other studies would then implicate Cdc42 in intracellular trafficking events (Harris and Tepass, 2010). The interaction of Cdc42 with another kinase target, ACK (for activated Cdc42-associated tyrosine kinase), was suggested to be involved in the down-regulation of the EGF receptor (EGFR) (Lin *et al.*, 2006). Moreover, the role of Cdc42 in extending EGFR lifetime may have provided the most direct evidence for the involvement of this GTPase in cell growth control. A hyperactivated Cdc42 mutant (see below) was shown to influence EGFR interactions with the E3 ubiquitin ligase c-Cbl, which catalyzes receptor ubiquitination and degradation (Feng *et al.*, 2006; Wu *et al.*, 2003). This was the result of the interaction of Cdc42 with the Cool-1 (for Cloned-out-of library)/ β -Pix (for Pak interactive exchange factor) protein, which also binds to c-Cbl. When a ternary complex was formed between Cdc42, Cool-1, and Cbl, the latter was unable to bind to EGFR and catalyze its degradation and down-regulation (Figure 6).

Many of the processes regulated by Rho family GTPases – cell cycle progression, transcriptional activation, cell survival, cell migration and invasion, vesicle trafficking – are important during oncogenesis. However, in contrast to the Ras GTPases, which are constitutively activated by point mutations in ~30% of human tumors (Fernández-Medarde and Santos, 2011), mutations in Rho GTPases are rare. Instead, many tumors show increased expression of Rho proteins, along with altered expression of the GEFs, GAPs, and GDIs that control their activity. With 20 human Rho members regulated by more than 80 GEFs, ~70 GAPs, and 3 GDIs, and with >70 downstream effectors, establishing the contributions of Rho signaling to cancer development has been a challenging research undertaking. However, early *in vitro* studies of cellular transformation have now been complemented with several mouse models, and a picture of Rho GTPase contribution to tumor progression *in vivo* is beginning to emerge (Figure 7).

Figure 5 Schematic of the mammalian targets of Cdc42.

Figure 6 Model of the Cdc42-mediated regulation of EGF receptor interactions with c-Cbl. EGF receptor activation stimulates GDP-GTP exchange on both Ras and Cdc42, resulting in the formation of Cdc42•GTP-Cool-1-Cbl complexes and signaling through the Ras-ERK pathway. When the Cdc42-Cool-1-Cbl complex disassembles, Cbl can then bind to the EGF receptor and is phosphorylated, thus enabling Cbl to function as an ubiquitin E3 ligase that catalyzes receptor ubiquitination and degradation.

Figure 7 Contributions of Rho GTPases to different stages of tumorigenesis. RhoA, RhoC, Rac1, and Cdc42 can promote cell proliferation and, through the upregulation of NF κ B, protection from apoptosis. During the development of benign tumors, RhoA, RhoC, and Rac1 can also contribute to the loss of cell polarity and cell junctions. Increased cellular motility and invasion through the basement is driven by RhoA, RhoC, Rac1, and Cdc42. RhoC signals to increase expression of angiogenic factors, and RhoA, RhoC, and Rac1 play important roles in intravasation and metastasis.

Rho GTPases in Oncogenic Transformation

Members of the Rho family of GTPases were initially identified on the basis of their homology with the *Ras* oncogenes, raising

the question of whether the Rho proteins might also play important roles in oncogenesis. In fact, several of the GEFs that activate Rho GTPase signaling were found in screens for proteins that cause cellular transformation. The founding member

of the largest family of Rho GEFs, Dbl, was identified in 1985 as an oncogene in a screen of genomic DNA from a human diffuse B-cell lymphoma (Eva and Aaronson, 1985; Hart *et al.*, 1991). Similar screens for transforming proteins identified other GEFs of the Dbl-family, including Vav, Ect2, and Tiam1 (Cook *et al.*, 2013). Subsequently it was found that these Dbl-family members all contained an activating N-terminal truncation that had arisen as a cloning artifact (Cook *et al.*, 2013). Nevertheless, these early results provided strong evidence that aberrant Rho GTPase signaling could contribute to cancer development.

The first studies to probe the oncogenic potential of individual Rho GTPases made use of constitutively active or dominant-negative variants of these proteins. Substitutions analogous to those found in oncogenic Ras (e.g., G12V and Q61L) abolish the intrinsic GTP hydrolysis activity of Rho GTPases, resulting in constitutively GTP-bound, active proteins (Khosravi-Far *et al.*, 1995). A distinct type of activating mutation is based on the Ras F28L variant, which shows reduced binding affinity for guanine nucleotides and thus is referred to as 'fast-cycling' (Reinstein *et al.*, 1991). Because intracellular GTP is considerably more abundant than GDP, this substitution results in the GTPase being mostly GTP-bound but still able to function as a molecular switch. The final class of mutation is based on the S17N variant of Ras, which has a dominant-negative phenotype. This substitution promotes a nucleotide-free state of the GTPase, which binds GEFs with higher affinity than the native protein and consequently inhibits GEF function (Feig, 1999).

A series of studies in the mid-1990s demonstrated that Rho, Rac, and Cdc42 are all essential for Ras-mediated transformation of fibroblasts (Sahai and Marshall, 2002). Expression of dominant-negative variants of any one of these Rho proteins is sufficient to block Ras-driven oncogenesis. Rho GTPases are also required for the transforming activity of numerous other oncoproteins, including receptor tyrosine kinases, Dbl-family members, and G protein-coupled receptors (Boerner *et al.*, 2001; Sachdev *et al.*, 2001; Whitehead *et al.*, 2001). In addition to Rho signaling being required for transformation by multiple oncogenes, ectopic expression of constitutively active or fast-cycling variants of some Rho GTPases, including RhoA, Rac1, and Cdc42, is sufficient to transform fibroblasts (Vega and Ridley, 2008).

Rho GTPases in Mammalian Tumors

Although constitutively activated Rho GTPases can promote cellular transformation *in vitro*, these mutations have generally not been found in human tumors. Similarly, the N-terminal truncation of Dbl-family GEFs, which is potently transforming *in vitro*, has not been found to occur in human cancer. However, aberrant Rho GTPase function is common in cancer, and is typically driven by altered expression of Rho proteins, and their regulators (Vega and Ridley, 2008). Abnormal expression levels of several Rho GTPases, including RhoA, RhoB, RhoC, Rac1, Rac2, Rac3, and Cdc42, have been detected in human tumors (Karlsson *et al.*, 2009), and overexpression of Rho GEFs, including Ect2, P-Rex, Tiam1, and Vav1 is also common (Cook *et al.*, 2013). Some RhoGAPs appear to function as

tumor suppressors, and genomic deletion of the gene encoding DLC1 occurs in hepatocellular carcinoma and many other malignancies. Altered expression of downstream effectors also occurs. For example, the Rac1/Cdc42 effector PAK is upregulated in some breast cancers, and the Rho effector ROCK is upregulated in advanced testicular cancers (Ellenbroek and Collard, 2007).

RhoA overexpression is associated with progression of many cancers, and has been implicated in all stages of cancer development from cellular transformation to metastasis. It promotes G1-S cell cycle progression by suppressing expression of the p21 and p27 cell cycle inhibitors along with multiple INK4 family tumor suppressors (Zhang *et al.*, 2009), and also plays important roles in amoeboid cell migration through the effector ROCK (Vega and Ridley, 2008). Ectopic overexpression of RhoA induces preneoplastic transformation and immortalization of primary mammary epithelial cells (Zhao *et al.*, 2009), and forced overexpression in an ovarian carcinoma cell line significantly increases invasiveness *in vitro* and peritoneal dissemination of tumor cells in nude mice (Horiuchi *et al.*, 2008). Reciprocally, knockdown of RhoA expression inhibits cell cycle progression and proliferation of gastric cancer cells and breast cancer cell lines (Wang *et al.*, 2010; Zhang *et al.*, 2009). Like RhoA, RhoC can induce transformation of some cell types (Xie *et al.*, 2013), but its most important function in cancer development is probably as a driver of cellular invasion and metastasis, and it can additionally stimulate the production of angiogenic factors (Merajver and Usmani, 2005). *Rhoc* knockout mice are viable with no overt phenotype, and are born at a Mendelian ratio (Hakem *et al.*, 2005). The contribution of RhoC to oncogenesis was investigated by crossing the mice with Polyomavirus Middle T mice, which develop palpable mammary tumors at ~50 days of age and lung metastases at ~70 days of age. Onset, frequency, and size of the primary lesions were unaffected by RhoC loss, but the RhoC-null mice showed a dramatic decrease in the size and number of lung metastases at 110–140 days of age (Hakem *et al.*, 2005).

In contrast to RhoA and RhoC, several studies have indicated that RhoB functions as a tumor suppressor, and its expression is downregulated in certain cancers (Karlsson *et al.*, 2009). RhoB-null mice are viable and born at a Mendelian ratio (Liu *et al.*, 2001). In a classical carcinogenesis test, in which skin tumors are initiated by DMBA/TPA application, RhoB-null mice developed more tumors than heterozygotes. When RhoA, RhoB, or RhoC were ectopically overexpressed in gastric cancer lines, RhoA promoted proliferation, RhoC promoted migration and invasion, whereas RhoB inhibited proliferation, migration, and invasion (Zhou *et al.*, 2011). Given that RhoA, RhoB, and RhoC share many effectors, it is likely that their different contributions to oncogenesis are based at least in part on their intracellular localization. RhoA and RhoC are localized to the plasma membrane, whereas RhoB is found mainly at endosomal membranes, and it is possible that it functions as a tumor suppressor by regulating delivery of signaling proteins including growth factor receptors to specific intracellular compartments (Vega and Ridley, 2008).

Rac1 promotes cell cycle progression by stimulating expression of cyclin D1, and transmits an anti-apoptotic signal by activating NF κ B (Gastonguay *et al.*, 2012). The contribution

of Rac1 to cell invasion and migration varies with physiological setting: active Rac1 can inhibit invasion by strengthening epithelial cell–cell contacts, but can also promote a more migratory phenotype by mediating the loss of adherens junctions (Vega and Ridley, 2008). Rac1 knockout in mice is embryonic lethal (Sugihara *et al.*, 1998), and therefore conditional knockout models have been generated. When oncogenic K-Ras was expressed in lung epithelial cells, mice with a conditional Rac1 deletion showed reduced tumor burden and prolonged survival (Kissil *et al.*, 2007). Rac1 is unusual among the Rho GTPases, in that it is frequently mutated in human cancer (Hodis *et al.*, 2012; Krauthammer *et al.*, 2012). The activating P29S substitution is the third most common alteration in melanoma, after mutations in *BRAF* and *NRAS*, strongly implicating *RAC1* as an oncogene in this malignancy. Expression of the Rac1 GEF Tiam1 is also upregulated in melanoma and other cancers (Cook *et al.*, 2013), and Tiam1 deficiency inhibited tumor formation and growth in mice after DMBA/TPA application (Malliri *et al.*, 2002).

The role played by Cdc42 in oncogenesis is complex and likely varies with physiological context. Cdc42 promotes cell survival, cell cycle progression and mitosis, and like Rac1 can regulate NF κ B and other transcription factors including JUN, STAT3 and SRF (Olson *et al.*, 1995; Stengel and Zheng, 2011). Hyperactive Cdc42 is able to induce cellular transformation *in vitro*, and Cdc42 is overexpressed in several cancers (Stengel and Zheng, 2011). However, mouse models are yet to demonstrate a tumor-promoting role for Cdc42. In a hepatocyte-specific deletion model, tumor nodules develop in the liver of mice by 6 months of age (Van Hengel *et al.*, 2008). In all mice, these subsequently develop into hepatocellular carcinoma with metastases to the lung. It is likely that tumorigenesis in this case is a consequence of chronic liver damage, rather than being directly driven by Cdc42 loss; indeed, Cdc42 is upregulated in human hepatocellular carcinoma (Stengel and Zheng, 2011). The dual function of Cdc42 in establishing and maintaining cell polarity, but also in transmitting mitogenic signals, likely underlies the conflicting evidence for its roles in cancer development and progression.

Rho GTPases and Cancer Cell Metabolism

Rho GTPases have recently been implicated in the reprogramming of cellular metabolism that occurs during malignant transformation. A key metabolic adaptation exhibited by many cancer cells involves the pathways that utilize glutamine (Lukey *et al.*, 2013). During cellular proliferation, the TCA cycle intermediate citrate is exported from mitochondria in order to generate cytosolic acetyl-CoA for lipid biosynthesis. Under these conditions, many cells upregulate a mitochondrial metabolic pathway to replenish the carbon that has been lost from the TCA cycle (anaplerosis). Glutamine is converted by the enzyme glutaminase (GLS) to glutamate, which in turn is deaminated by glutamate dehydrogenase (GLUD1) to yield the TCA cycle intermediate α -ketoglutarate. The discovery that many cancer cells are addicted to this metabolic pathway has raised the possibility of targeting these enzymatic activities as a therapeutic strategy against cancer (Lukey *et al.*, 2013). Rho GTPases are able to support TCA cycle anaplerosis by

upregulating GLS activity in the mitochondrion (Wang *et al.*, 2010). Transformation of fibroblasts by oncogenic Dbl, or by fast-cycling variants of RhoC, Rac1, or Cdc42, results in a marked increase in mitochondrial GLS activity. Human breast cancer lines with deregulated Rho GTPase signaling also show elevated GLS activity, and knockdown or inhibition of GLS in these cells strongly inhibits proliferation. The pathway through which Rho GTPases signal to upregulate glutamine metabolism has not yet been fully elucidated, although the NF- κ B member p65 has been implicated as a critical component (Wang *et al.*, 2010).

Rho GTPases and Cancer Cell Microvesicles

Cancer cells can influence their environment through a variety of mechanisms, including the secretion of soluble factors and the release of two classes of extracellular vesicles, known as exosomes and microvesicles (Raposo and Stoorvogel, 2013). Exosomes are 40–100 nm vesicles that are released from a cell when a multivesicular endosome fuses with the plasma membrane, whereas microvesicles are typically larger (up to 3 μ m in diameter) and are shed directly from the plasma membrane. Both exosomes and microvesicles carry a diverse cargo from the parent cell, and when these structures fuse with a recipient cell the contents are released. The cargo of microvesicles includes cell surface receptors, downstream signaling proteins, and metabolic enzymes, and these components can promote transformed behavior in recipient cells (Raposo and Stoorvogel, 2013). Rho GTPase signaling drives the production of microvesicles, particularly downstream of RhoA and ROCK (Li *et al.*, 2012).

Concluding Remarks

The first established roles for the Rho GTPases involved regulation of the actin cytoskeleton. Over the last two decades, it has become clear that Rho family members signal to influence diverse processes, including cell cycle progression and gene expression. It has long been appreciated that many of these signaling pathways would have important consequences in cancer development and metastasis. This has been borne out by the construction of animal models, and by the discovery of recurring Rac1 mutations in human malignancies. Recent discoveries implicate Rho proteins in unexpected areas, including the regulation of glutamine metabolism and the generation of microvesicles. All of this points to the possibility of developing novel therapeutic strategies to interfere with these Rho GTPase-driven processes that promote and support the malignant state.

Key Points

- The 20 mammalian Rho GTPases act as molecular switches that regulate many important processes in cell biology.
- Early studies implicated the Rho GTPases as regulators of the actin cytoskeleton, through effectors such as mDia, WASP, WAVE, ROCK, and PAK.

- By regulating cytoskeletal dynamics, the Rho GTPases influence cell shape, cell migration, vesicle trafficking, and cytokinesis.
- Rho GTPases also signal to regulate gene expression, cell cycle progression, cell survival, cellular metabolism, and extracellular vesicle production.
- Rho GTPases are frequently deregulated in cancer. Many are overexpressed or hyperactivated, while some (e.g. RhoB) are typically downregulated. Rac1 has recently been implicated as an oncoprotein in melanoma.

Glossary

Cell fate determinants Asymmetrically localized proteins that are required for cell fate specification. In *Drosophila* proteins such as Numb, Prospero, and Brat are localized at the basal side of neuroblasts ready for asymmetric division.

Epithelial–mesenchymal transition The epithelial–mesenchymal transition (EMT) is an orchestrated process by which polarized epithelial cells are converted to motile mesenchymal cells. During this process cell–cell and cell–extracellular matrix interactions are altered, the cytoskeleton is reorganized, and a new transcriptional program is induced to maintain the mesenchymal phenotype. EMT is essential for normal embryonic development, but it is also associated with metastasis and tumor progression.

Imaginal discs Larval or pupal epithelial precursors of most adult *Drosophila* organs. Imaginal discs are formed by two contiguous epithelia, a columnar layer and a squamous layer; together they form a bag-like folded epithelium. Each imaginal disc forms a separate structure, e.g., there is a

separate imaginal disc that forms wings while another imaginal disc forms legs.

MDCK (Madin-Darby canine kidney) cells MDCK cell line derived from dog kidney. Used as model for studying trafficking and establishment of cell polarity in epithelia.

Mitotic spindle The mitotic spindle is the macromolecular machine that segregates chromosomes to two daughter cells during mitosis. The spindle consists primarily of microtubules, polarized filaments composed of α/β -tubulin heterodimers arranged in a head-to-tail configuration within protofilaments.

Scaffold protein A multivalent protein that is known to interact and/or bind with multiple members of a signaling pathway. They help coordinate the location of proteins to specific areas of the cell and tether them into complexes, thus enhancing the efficiency and/or specificity of cellular signaling pathways.

Transmembrane protein Integral membrane protein that spans from one side of a membrane through to the other side of the membrane.

Basic Principles of Cell Polarity and Common Mechanisms of Control

Cell polarity can be defined as an asymmetry in molecular composition or structure between two sides, thus defining a polarity axis along which cellular processes will be differentially regulated. Evidence of polarity can be detected across evolutionary history, from the simplest unicellular organisms, such as the bacterium *Escherichia coli* and the budding yeast *Saccharomyces cerevisiae*, up to the most complex multicellular organisms, including flies, plants, and animals. Cell polarity is therefore a universal attribute of almost all cells. Whereas in unicellular organisms polarity apparently plays a role in control of lineage senescence by ensuring differential inheritance of damaged material at cell division (Macara and Mili, 2008), in multicellular organisms it is responsible for differential cell fate specification in asymmetric divisions as well as for a wider range of cellular functions. For example, neurons are highly polarized cells with segregated domains specialized for either receiving (dendrites) or transmitting (axons) cellular signals. Mesenchymal cells need to acquire a front-to-back polarity in order to migrate, while epithelial cells display both apical–basal and planar polarity.

A great effort has been made in the last 50 years to investigate cell polarity, first in simple model systems such as yeast, the worm *Caenorhabditis elegans*, and the fruitfly *Drosophila melanogaster*, and later in mammals, by the combination of different approaches, including traditional genetic and biochemistry techniques as well as modern live imaging and computational methods (Slaughter *et al.*, 2009; Sawa, 2012;

Tepass, 2012). Three important pieces of evidence have emerged from these studies. First, irrespective of the organism or cell type, the establishment of cell polarity relies on general and common steps that need to be integrated: (1) a polarity cue, both intrinsic and external; (2) dedicated polarity determinants that are localized to specific domains of the plasma membrane and act to establish polarity; (3) polarized trafficking of proteins and lipids that deliver cargo to specific membrane domains; and (4) transduction of polarity information. Second, even more fascinatingly, studies in recent years have shown that some polarity players have highly conserved roles across animal species. One example involves the Cdc42 small GTPase, which acts as a key molecule in orchestrating the establishment of cell polarity in many well-studied systems, including yeast cells, *Drosophila* neuroblasts, neurons, and epithelial cells. Cdc42 integrates the variety of extra- and intracellular signals received by the cell and, once activated, can potentially interact with several distinct target proteins in order to select a single appropriate polarity axis (Etienne-Manneville, 2004). Another example is that constituted by Par3, Par6, and the atypical protein kinase C aPKC, forming the Par complex (Goehring, 2014). They were first identified in the *C. elegans* zygote by pioneering genetic screens showing that mutants in ‘partitioning defective’ (*par*) genes fail to establish the correct anterior–posterior (AP) cortical polarity axis. Par mutants do not divide asymmetrically but result in two equal-sized anterior and posterior daughter cells (Kemphues *et al.*, 1988). As far as we know, the Par complex is conserved in the *Drosophila* oocyte and epithelia and in mammalian epithelial cells, where it functions to regulate cell

polarity and proliferation, but it does not exist in yeasts or plants. This divergence may be ascribed to the different mechanisms by which a plant or animal cell controls cell surface tension, with the former using cell-wall glucans or cellulose to modify surface tension, and the latter maintaining surface stability through a contractile actomyosin cortex (Li and Bowerman, 2010). A third principle hence arises: regulatory elements, such as the Par module, and cytoskeletal polymers cooperate and influence each other to generate and maintain asymmetry. For instance, in a *C. elegans* one-cell embryo and in mammalian polarized cells polarity molecules control the directional and polarized assembly of actin filaments. On the other hand, in the *Drosophila* oocyte the cytoskeleton is responsible for shaping the distribution and activity of signaling molecules (Goehring and Grill, 2013). The majority of polarity systems can therefore be considered mechanochemical, since cellular asymmetry is controlled by the coupling of mechanical processes and chemical elements, like diffusible species forming a gradient maintained by self-amplifying feedback (Howard *et al.*, 2011).

In the following sections we will dissect each of the general steps of polarity establishment outlined above, giving a molecular description of the key players and discussing their interplay in epithelial cells.

Epithelial Cells

Epithelial cells are the most common cell type in multicellular organisms. They form organized layers, either simple or stratified, that separate the body from the outside world (e.g., epidermis) and subdivide the body into morphologically and physiologically different compartments (e.g., intestinal and lung epithelium). The function of epithelia is to provide a barrier between the inside and outside of the organism, and to allow vectorial transport of fluid or directed secretion of specialized components from one side to the other. To achieve this function, epithelial cells must be highly polarized. They are indeed characterized by an apical plasma membrane domain, facing the external environment, and a basolateral domain, contacting neighboring cells and the extracellular matrix (ECM) with different protein and lipid composition. Epithelial cells differ from other polarized cell types, such as the *C. elegans* embryo and *Drosophila* oocytes having two opposite cortical domains as well, because they form specialized cell junctions with neighboring cells that mark the boundary between the apical and lateral domains. The differential positioning of components (membrane domains and organelles) along the apical-basal axis of an epithelial cell is referred to as apical-basal polarity.

Apical-Basal Polarity of Epithelial Cells

The mechanisms that promote the establishment and maintenance of epithelial cell polarity are not completely understood, and can vary in different epithelial cells in mammals and other model organisms. However, work over the last two decades has pointed to intercellular junctions and apical-basal polarity complexes as important mediators of polarity in simple epithelial cells in both vertebrates and invertebrates.

Mediators of Epithelial Cell Polarity

Intercellular adhesion complexes

Two types of intercellular junctions are established at the level of the lateral surface of epithelial cells: tight junctions (TJs) and adherens junctions (AJs). Although made up of different proteins, both junctional complexes associate with actin, and formation and maturation of cell-cell contacts involves reorganization of the actin cytoskeleton. Both TJs and AJs are composed of transmembrane proteins, responsible for the adhesion of adjacent cells, and of intracellular scaffolding proteins for anchorage to the cytoskeleton. In mammalian epithelia TJs localize apically to AJs at the border of the apical and basolateral domain (Figure 1). In *Drosophila* epithelia the septate junction (SJ), the structure analogous to TJs in invertebrates, sits basal to AJs, while *C. elegans* epithelial cells have a single apical junction that acts as both AJs and TJs. TJs form a belt-like structure and provide both a fence function, to limit the diffusion of proteins and lipids between apical and basolateral membrane domains, and a barrier function, which restricts the passage of molecules between cells. TJs consist of a number of integral proteins, such as claudin, occludin, and junctional adhesion molecules (JAMs), and associated cytoplasmic proteins such as zonula occludens-1 (ZO-1) and its homologs ZO-2 and ZO-3, which in turn interact with F-actin (Tsukita *et al.*, 2009; Figure 1). AJs provide the main mechanical link between neighboring epithelial cells. AJs consist of two basic adhesive units, the cadherin-catenin and nectin-afadin complexes (Niessen and Gottardi, 2008). Classical cadherins mediate strong cell-cell adhesion by a homophilic calcium-dependent binding of their extracellular domain. Intracellularly, they bind through β -catenin to α -catenin, which in turn interacts with actin-binding proteins (actin-BP) (Kobiela and Fuchs, 2004; Figure 1). Nectins link AJs to the actin cytoskeleton through the scaffolding protein afadin (AF6) (Takai and Nakanishi, 2003; Figure 1). In addition, nectins bind to ZO-1 and α -catenin, thus providing a link between AJs and TJs.

Polarity complexes

Two main apical and one basolateral groups of proteins have been found to be involved in the establishment of cell polarity (Figure 1). The first major apical polarity complex is the Par complex, identified in *C. elegans* embryonic lethal mutants and conserved in *Drosophila* oocytes and neuroblasts and mammalian epithelial cells. The Par complex, which establishes the apical-basal membrane border, consists of Par3 (Bazooka, in *Drosophila*) and Par6, which are the scaffolding proteins, and the kinase aPKC, core effector of the complex. Other proteins, including Cdc42 GTPase and Rac1, are considered part of the same group (Lin *et al.*, 2000). The second apical polarity complex is the Crb complex, which controls the extension of the apical surface (Roh *et al.*, 2003). Crb (Crumbs 1–3 in vertebrates) forms a complex with protein associated with Lin Seven 1 (PALS1; Stardust, in *Drosophila*) and PALS1-associated tight junction protein (PATJ). In both *Drosophila* and vertebrate epithelial cells, the Crb complex is enriched at the apical margin of the lateral domain. The Crb complex interacts with the Par complex through the interaction of PALS1 to Par6. In *Drosophila* and mammalian

Figure 1 Establishment of cell polarity and junctional complexes in mammalian epithelial cell. From left to right, maturation of primordial junctions into distinct TJs and AJs during epithelial cell polarization. The process requires the exclusion of Par3 through the localized activation of Rac1 GTPase at intermediate stages of polarization. Upon phosphorylation by aPKC, Par3 accumulates at TJs. The Par and Crb complexes establish the apical and the apical/lateral membrane, whereas the Scrib complex defines the basolateral plasma membrane domain. On the right, overview of the antagonistic interactions between the Par complex (orange), the Crumbs complex (red), and the Scribble complex (green).

epithelia, Par6/aPKC colocalize with the Crb complex, while most Par3 localizes at TJs, slightly basally to the Crumbs complex. One exception is the primary epithelium of *Drosophila* (see below), where Bazooka is enriched at the level of the AJs.

The basolateral complex is the Scrib complex, composed of Scribble (Scrib), lethal giant larvae homolog (Lgl), and discs-large homolog (Dlg). The Scrib complex localizes to AJs in mammals (with SJs in *Drosophila*) and defines the basolateral membrane domain (Laprise et al., 2004). At least in *Drosophila*, another group of proteins, the Yurt/Coracle (Yrt/Coracle) group, has been identified as a novel additional player in polarity establishment. The Yrt/Coracle group promotes basolateral membrane stability by negatively interacting with the apical determinant Crumbs (Laprise et al., 2009). It is important to note that the Yrt/Coracle group is essential for epithelial polarity during organogenesis but not in late embryogenesis, when apical and basolateral markers can be normally segregated even in the absence of Yrt/Coracle. This implies the existence of yet unknown polarity proteins that act to define lateral membrane stability in late-stage embryos. Notably, the mammalian Yrt ortholog binds to Crb and contributes to epithelial organization (Laprise et al., 2006).

Initiating Cues of Polarization

Epithelial cells use different cues to establish apical-basal polarity. Most of our knowledge has come from studies on cultured epithelial cells, for example, Madin-Darby canine kidney (MDCK) cells grown in a two-dimensional (2D) system, i.e., as a monolayer, and in three-dimensional (3D) system, where they form spheroid structures termed cysts, consisting of a single layer of cells with an apical surface lining an inner lumen and a basolateral surface in contact with the ECM (Zegers et al., 2003; Martin-Belmonte and Mostov, 2008; Figure 2(d)). In these systems the initiating polarity cue is provided by contact with the basement membrane (BM) and with neighboring cells. BM collagen activates – through $\beta 1$ -integrin – Rac1, which mediates laminin organization and assembly of the nascent BM (Yu et al., 2005). In turn, assembly of laminin activates Rac1, thus generating a positive feedback loop that reinforces the orientation of this signaling pathway. A similar mechanism of matrix-dependent orientation of polarity acts in *Drosophila* follicular epithelium (Denef et al., 2008), and it has been also revealed in mammalian systems *in vivo*, such as in the mammary gland (Naylor et al., 2005). Remarkably, an outstanding article recently published unveils

Figure 2 Polarized trafficking and lumen formation in 3D-MDCK cysts. (a–c) Scheme of vectorial trafficking. (a) In unpolarized cells apical membrane components (like PCX) face the ECM, and they need to be internalized and transported to their new destination, in a process of inversion of polarity. β 1-integrin mediates this inversion through its interaction with the ECM, thus triggering MT reorientation, Rac1 inhibition, and induction of endocytosis. Once endocytosed, the apical components are targeted to Rab11-positive AREs. Par3 is present at TJs. (b) Rab11-positive AREs travel to the lumen initiation site (*), probably by association with kinesins (upper right) along the microtubules, which have been previously reoriented. Slp2-a binds to PtdIns(4,5)P₂ enriched at the forming apical membrane and clusters apically destined vesicles in a Rab27a/b-dependent fashion. Concomitantly, Slp4-a bridges Rab27-Rab8 and the apical SNARE syntaxin 3 to promote vesicle tethering and fusion at the lumen initiation site (lower left). The exocyst complex carries out docking of vesicles to the lumen initiation site. Par3 is delivered to the lumen initiation site, a process reinforced by the Crb complex. (c) Once the vesicles reach the lumen initiation site, a tight junction–delimited lumen begins to appear. Cdc42 is activated by aPKC/Par6 in the apical membrane, in collaboration with Tuba. The Par complex recruits PTEN, which maintains the PIP2/PIP3 segregation between the AP and BL membranes. At this stage lumen filling takes place by paracellular transport of ions through the TJs. (d) Time-course analysis of lumen formation in 3D-MDCK cysts. AP and BL membranes are defined by green (Spl2) and red (actin) staining, respectively. Nuclei are depicted in blue (unpublished data). AP, apical; BL, basolateral; ECM, extracellular membrane; PCX, podocalyxin.

the importance of the BM niche surrounding epiblast (EPI) cells in guiding the polarization of these amorphous cells into rosette-like structures such as mouse blastocyst implants (Bedzhov and Zernicka-Goetz, 2014). The BM provides polarization cues that signal through β 1-integrin receptors to orient the establishment of basal–apical axis of the epiblast cells, which later change their shape and organize in a rosette with a small luminal space, precursor of the pre-amniotic cavity. The ECM proteins present in the matrigel provide cues similar to those of the BM in the embryo and are thus sufficient to induce polarization of 3D cultured ES cells, which organize in spheres strongly resembling the EPI rosettes of the peri-implantation embryos (Bedzhov and Zernicka-Goetz, 2014).

In cultured cells, an additional polarization cue comes from neighboring cells. Epithelial cells extend thin protrusions

filled by actin filaments in order to contact neighboring cells and build up cohesive layers of cells. The first cell–cell contact sites, known as ‘puncta,’ are positive for both typical AJ and TJ proteins (Tsukita *et al.*, 2009) and probably serve as a ‘landmark’ or ‘positional cue’ for membrane growth and recruitment of other integral and peripheral membrane proteins. These primordial adhesion sites later mature to form distinct AJs and TJs (Figure 1). Evidence in mammalian embryonic development and MDCK cells cultures suggests that AJs are required for cell polarization. However, it is noteworthy that some cell types can polarize in the absence of intercellular contacts, as is the case of *Drosophila* multinucleated embryonic cells which are forced into contact by cellularization, i.e., they undergo a process of plasma membrane invagination in order to compartmentalize the nuclei and generate single epithelial

cells (Lecuit, 2004). As we will see in the following section, the polarity cue acting in *Drosophila* primary epithelium seems to be provided by the cytoskeleton, and not by extrinsic cell–cell adhesion signals.

Proteins Interplay Organizing Apical–basal Polarity

In the *C. elegans* zygote the anterior (Par3/Par6/aPKC) and posterior (Par1/Par2/Lgl) polarity determinants act in a mutually antagonistic manner to exclude one another from the plasma membrane. Similarly, the generation and maintenance of distinct apical and basolateral domains in epithelial cells depend on mutually antagonistic interactions between the three polarity complexes described above and on their interaction with adhesion proteins. The three polarity complexes interact by a system of mutual phosphorylation-dependent exclusion that ensures their correct position in different membrane domains. The formation of the apical cellular domain relies on the activity of the kinase aPKC. Par3 is initially recruited to the plasma membrane of unpolarized cells through its binding to the nectin–afadin complexes (Ooshio *et al.*, 2007), but it will be later excluded from this region in order to allow the maturation of the primordial adhesion sites (Figure 1). E-cadherin enriched at mature AJs triggers phosphorylation of aPKC, which in turn phosphorylates Par3. Once phosphorylated, Par3 dissociates from aPKC and accumulates at TJs (Nagai-Tamai *et al.*, 2002; Figure 1). In addition, aPKC phosphorylates Crumbs at the apical cortex to control the extension of the apical surface and/or apical junction assembly. The formation of the basolateral domain depends on the activity of the Scribble complex and the kinase Par1. Lgl can physically interact with Par6/aPKC early during cell–cell contact formation, thus blocking the formation of the Par3/Par6/aPKC complex. Upon phosphorylation by aPKC, Lgl dissociates from the apical membrane cortex and distributes to the lateral membrane, where it may interact with Dlg and Scrib (Yamanaka *et al.*, 2003). Furthermore, Par1 phosphorylates Par3 at the basolateral domain, thus dissociating it from Par6/aPKC and excluding the Par6/aPKC complex from this domain (Suzuki *et al.*, 2004; Figure 1).

Apical–basal polarity is generated in quite a different way in the primary epithelium of *Drosophila*, where Bazooka acts upstream of the AJs. As the plasma membrane invaginates to form single cells, Bazooka accumulates at apical/lateral margins of each cell before and independently of cadherin, thus acting as a primary landmark to position the AJs. Bazooka then clusters E-cadherin and the nectin-like protein Echinoid to form the AJs. Bazooka localization depends on the apical actin network and on dynein-dependent transport of Bazooka along apical–basal microtubules (Harris and Peifer, 2005).

Polarized Trafficking Machinery

Membrane trafficking contributes to the generation of cortical epithelial cell polarity. Newly synthesized components of the plasma membrane are sorted in the trans-Golgi network (TGN) and use exocytotic pathways to be delivered to specific domains of the plasma membrane. After surface delivery, apical and basolateral cargoes can be internalized and sorted

into either late endosomes (LE)/lysosomes for degradation, or recycling endosomes (RE) for recycling back to either membrane domain. Endocytosis and recycling from both surface domains are thus essential to maintain the composition of the different membrane domains. Endocytosis ensures the appropriate levels of plasma membrane proteins that control apical–basal polarity, such as Crumbs, which is constantly endocytosed at the basolateral membrane to avoid apical expansion of *Drosophila* follicle epithelium. Recycling allows the proper repositioning of apical and basolateral proteins that require transcytosis to reach their correct membrane domain. As an example, Crumbs is recycled back to the plasma membrane through the action of Rab11 GTPase and contributes to AJs remodeling during embryogenesis. Indeed, disruption of the Rab11 function in the *Drosophila* embryo leads to fragmentation and loss of AJs, and is preceded by loss of Crumbs from the apical domain (Roeth *et al.*, 2009).

Membrane trafficking requires sorting determinants present in the protein sequence, which are decoded by the transport machinery that ensures correct membrane delivery. Apical sorting signals have been localized to all portions of apically destined proteins: the extracellular, transmembrane, and cytoplasmic domains. Apical sorting signals include N-glycans and O-glycans, the glycosyl phosphatidylinositol (GPI) anchor, and specialized transmembrane domains such as that of influenza hemagglutinin. Moreover, some apical proteins associate with lipid rafts, which are formed by cholesterol and glycosphingolipids and act as functional sorting platforms. By contrast, basolateral sorting signals are simple peptide motifs in the cytoplasmic tail of a protein, including tyrosine-based and dileucine-based motifs (Cao *et al.*, 2012). Vesicle traffic is dependent on the cytoskeleton and is driven by microtubule- and actin-based motors. Tethering of vesicles to both apical and basolateral plasma membrane domains has been shown to depend on different subunits of the exocyst, an eight-subunit complex first identified in yeast and conserved in *Drosophila* and mammalian cells (Oztan *et al.*, 2007; Zuo *et al.*, 2009). Finally, vesicle fusion is mediated by interaction between t-SNARE complexes on the target membrane, syntaxins, and v-SNARE complexes on the vesicle membranes.

Interestingly, an increasing body of evidence shows that polarity regulators act as important controllers of vesicle trafficking machinery. Genetic screens in *C. elegans* provided the first link between the Par complex, Cdc42, and regulation of endocytosis (Balklava *et al.*, 2007). In *Drosophila* neuroectoderm, loss of Cdc42 causes accumulation of apical proteins, including Crumbs, in sorting endosomes, probably owing to aPKC activity, a defect that in turn causes the disorganization of the AJs (Harris and Tepass, 2008). However, in other *Drosophila* tissues, such as imaginal discs, Cdc42 seems to play a role in AJs endocytosis through a Par-independent pathway involving actin polymerization. Recently, *par-5* has been identified in the *C. elegans* intestine as a controller of the subapical localization of Rab11-positive REs (Winter *et al.*, 2012).

Transcytosis and lumen formation

An instructive system to investigate the reciprocal interplay between polarity complexes and membrane trafficking is the formation of lumen, a structure found in many epithelial

organs of the body. 3D-MDCK cultures represent a good model to explore the process of *de novo* lumen generation, which depends on a transcytotic pathway (Rodriguez-Fraticelli *et al.*, 2011; Apodaca *et al.*, 2012). In unpolarized MDCK cells aggregates, apical membrane proteins, such as podocalyxin and the Crb complex, are distributed at the periphery. They are first endocytosed and transported in vesicles toward Rab11-positive apical recycling endosomes (ARE), a process regulated by the actin cytoskeleton (Madrid *et al.*, 2010; Figure 2(a)). Then apical membrane proteins travel to the lumen initiation site, probably by association with motor proteins (such as kinesins) that move through polarized microtubules. Their trafficking from ARE to the site of lumen initiation is regulated by the Rab family of GTPases, specifically by Rab11, Rab8, and its specific GEF Rabin8 (Bryant *et al.*, 2010; Figure 2(b)). Finally, the exocyst proteins Sec8, Sec10, and Sec15A facilitate the tethering of vesicles to the forming apical membrane. Synaptotagmin-like proteins 2a (Slp2-a) and 4a (Slp4-a) coordinate the spatiotemporal organization of vectorial apical transport to ensure that only a single apical surface occurs per cell (Galvez-Santisteban *et al.*, 2012). Exocytosis is also important for the initial recruitment of the Par3/aPKC complex to the lumen initiation site. Active Rab8 stimulates Cdc42 interaction with the exocytic carriers and its delivery to the forming apical membrane, where it activates the Par complex (Figure 2(b)). A similar type of transcytotic process has been observed *in vivo* in mouse mammary gland (Akhtar and Streuli, 2013). Furthermore, some aspects of the polarization process of EPI cells organizing into rosette-like structures attractively resemble lumen formation in 3D-MDCK cultures (Bedzhov and Zernicka-Goetz, 2014). EPI cells change their shape as a result of actomyosin constriction, transmitted through AJs, and aPKC and Par6 accumulate in the apical membrane in the center of the sphere. The small luminal space that appears in the center of the rosette is a result of charge repulsion of apical membrane proteins such as podocalyxin (Bedzhov and Zernicka-Goetz, 2014).

Phosphoinositides and polarized trafficking

Phosphoinositides and other lipids are essential for membrane trafficking and, ultimately, for generating epithelial polarity. As MDCK cells polarize in 3D cultures, *PtdIns(3,4,5)P₃* (PIP₃) concentrates at the basolateral membrane, whereas *PtdIns(4,5)P₂* (PIP₂) becomes restricted to the apical membrane (Cassama-Diagne *et al.*, 2006; Martin-Belmonte *et al.*, 2007). The lumen is formed at a previously basolateral cell–cell contact through the accumulation of PIP₂ via the lipid phosphatase PTEN, which converts *PtdIns(3,4,5)P₃* to *PtdIns(4,5)P₂* (Martin-Belmonte *et al.*, 2007), and the activity of the PI5K (Figure 2(c)). PIP₂ leads to the recruitment of active Cdc42 (Etienne-Manneville, 2004; Martin-Belmonte and Mostov, 2007), where it binds and activates the Par6/aPKC complex. PIP₂ is thus proposed to be the main determinant of apical identity. Moreover, PIP₂ directs the vectorial traffic of secretory vesicles to the lumen initiation site through Rab-GTPases and SLP2-a/SLP4-a (Galvez-Santisteban *et al.*, 2012; Yasuda *et al.*, 2012; Figure 2(b)). As in mammalian systems, apical membranes of *Drosophila* tubular epithelia are enriched in PIP₂ and mediate apical targeting through the recruitment of the formin-family protein Diaphanous (Dia) (Roussio *et al.*, 2013).

Cytoskeletal Rearrangements

Acquisition of apical–basal polarity entails an elaborate reorganization of microtubules and actin cytoskeleton. In mammalian epithelial cells, some microtubules are nucleated from microtubule organizing centers (MTOCs) such as the centrosome and are captured by the apical junction complex, thus generating a polarized network of cortical microtubules, with basally oriented plus-ends (Sugioka and Sawa, 2012). Rho-GTPases of the Par complex, such as Cdc42 and Rac, stimulate actin nucleators such as formin and Arp2/3 and suppress destabilizing factors. Additionally, Par3 present at TJs regulates the Rac exchange factor TIAM1, thus recruiting a ring of F-actin to the cell cortex adjacent to the AJs (Chen and Macara, 2005). Like mammalian Par3, Bazooka stabilizes the formation of an actin belt around the apical cell cortex in *Drosophila*. In the *C. elegans* embryo the asymmetric distribution of Par proteins along the anterior–posterior axis generates an asymmetry of force applied to the spindle, which results in the activation of the posterior pulling motors and the inhibition of the anterior motors (Colombo *et al.*, 2003).

Planar Cell Polarity

In addition to the apical–basal polarity, most epithelial tissues present a second type of polarity, which is in the plane of the tissue, perpendicular to the apical–basal axis. This type of polarity is known as planar cell polarity (PCP), and it can be found not only in epithelial tissues but also in mesenchymal sheets. PCP was first described in the *Drosophila* eye and wing imaginal disc (Adler, 2002). Although gene redundancy hampers the study of PCP generation in vertebrates, mutation and overexpression studies performed in recent years have revealed that many of the proteins linked to PCP in flies are evolutionarily conserved and have analogous roles in vertebrates. The most evident examples of mammalian epithelia with PCP features are ‘hairy’ organs such as the cochlear cells of the inner ear and skin/epidermis (Montcouquiol *et al.*, 2003; Guo *et al.*, 2004). In *Drosophila* and vertebrates, PCP controls the organization of cells within tissues and oriented cell division (see below). In addition, PCP shows an additional novel role, namely the regulation of polarized and directed cell movements. This process, known as convergent extension or cell intercalation, occurs during gastrulation (Wallingford *et al.*, 2002) and during tubular organ morphogenesis in vertebrates, such as in neural tube closure and renal tubule elongation (Mao *et al.*, 2011).

Molecular Basis

Genetic studies of *Drosophila* have revealed three major groups of PCP genes. The first group consists of the core PCP proteins, including *Frizzled* (Fz), *Dishevelled* (dsh), *Diego* (dg), *Van Gogh* (vang), *Flamingo* (fmi), and *Prickle* (pk). These proteins coordinate polarity between adjacent cells and amplify subcellular asymmetry, producing a local alignment of polarity. In the fly wing imaginal disc, vang and pk accumulate at the proximal side, while Fz, ds, and dg accumulate at the distal side (Zallen, 2007). Fmi is localized to both proximal and distal

Figure 3 Asymmetric distribution of core PCP proteins in *Drosophila* imaginal disc.

sides (Figure 3). Homologs of these genes have analogous subcellular locations, roles, and interactions in vertebrates. A second group of PCP genes, known as the Fat/Ds PCP group, consists of *fat*, *dachsous* (*ds*), *atrophin* (*atro*), and *four-jointed* (*fj*). Opposing expression gradients of *ds* and *fj* are thought to provide global directional information (Axelrod, 2009).

Downstream of the core PCP genes and *fat/ds* are the PCP effectors that are tissue-specific and convert PCP signals into the corresponding cellular response, such as physical remodeling, adhesion and movement, and orientation of the mitotic spindle (Wang and Nathans, 2007). Recent evidence has shown an exciting link between PCP and apical-basal polarity. To start with, core PCP proteins colocalize with AJs (Lindqvist *et al.*, 2010). In addition, Lgl has been reported to be involved in PCP signaling in *Drosophila* (Kaplan and Tolwinski, 2010), and Scrib has been shown to be an effector of the core PCP protein Vang in mammalian epithelial cell lines (Courbard *et al.*, 2009).

Relationship between Cell Polarity and Spindle Orientation Control

The orientation of the cell division plane is one of the mechanisms that coordinate the rate of cell division with cell fate choice and cell position. This coordination depends on the orientation of the mitotic spindle relative to a defined polarity axis, and it is essential for animal development, as in the case of epidermis. Basal epidermal cells are symmetrically dividing cells, and therefore their spindle is oriented in the plane of the tissue, thus shaping, expanding, and maintaining tissue morphology. At later developmental stages, in order to generate cellular diversity and stratification of the skin, cells start to divide asymmetrically, i.e., they need to align the spindle

parallel to the polarity axis so that basal cell fate determinants segregate into only one daughter cell (Knoblich, 2010).

It is worth highlighting that many of the genes controlling epithelial cell polarity also regulate spindle orientation. In the *C. elegans* zygote, the Par complex, a fundamental player in establishing AP cortical polarity axis, also drives spindle orientation (Kemphues *et al.*, 1988). Upon fertilization, the *C. elegans* zygote divides asymmetrically to generate a larger anterior cell and a smaller posterior cell. The orientation and positioning of the mitotic spindle depend on microtubules that emanate from the spindle poles and make contact with the cortical Par complex and the cortical polarity proteins LIN-5 and GPR1/2. These polarity factors are unequally distributed in the cell cortex, so they generate an asymmetric distribution of net pulling forces acting on the two centrosomes of the mitotic spindle (Betschinger and Knoblich, 2004).

In asymmetrically dividing *Drosophila* neuroblasts the apical Par complex is connected via Inscuteable (Insc) to the apical machinery composed of Mud and dynein, which generates pulling forces on the mitotic spindle (Schober *et al.*, 1999; Figure 4(a)). A similar pathway is used for spindle orientation in mammalian epithelial cells (Lechler and Fuchs, 2005). The initial attachment of the astral microtubules to the basolateral membranes has recently been shown to occur through IQGAP1 and EGFR proteins (Banon-Rodriguez *et al.*, 2014). In *Drosophila* neuroblasts a second pathway, involving Dlg and the kinesin motor protein Khc-73, has been shown to provide a parallel mechanism of spindle orientation through microtubule-capture or attachment (Bergstrahl *et al.*, 2013; Figure 4(a)). Also, aPKC phosphorylates cell fate determinants to exclude them from the apical cortex and to ensure that they are inherited by the ganglion mother cell (GMC) only (Atwood and Prehoda, 2009).

In *Drosophila* sensory organ precursors (SOP), the Mud-dynein complex has been shown to directly bind to the Frizzled-Dishevelled complex, thus providing the molecular link between PCP proteins and spindle orientation machinery (Segalen *et al.*, 2010; Figure 4(b)). These results highlight a striking example of convergent evolution of a shared signaling pathway (Mud-dynein) downstream of divergent upstream activators (Pins/Dsh).

Loss of Cell Polarity and Disease

Loss of cell polarity is a characteristic hallmark of cancer. When polarity is disrupted, cells may become unresponsive to growth inhibitory signaling and thus circumvent differentiation, senescence, and apoptosis, promoting cancer initiation. In addition, disruption of epithelial cell polarity is associated with loss of key components of intercellular junctions, which precedes cells undergoing epithelial-mesenchymal transition (EMT), a crucial step in metastasis (Nieto, 2013). In humans, more than 80% of tumors originate from epithelial tissues.

Exciting studies in *Drosophila* have clearly demonstrated that any perturbation of correct asymmetric cell division results in abnormal accumulation of dividing cells and cancer. The polarity proteins Lgl, Dlg, and Scrib, which control asymmetric division (see above), are therefore potent tumor

Figure 4 Molecular models for Pins- and Dsh-mediated spindle orientation. (a) The Par complex associates with Pins (Partner of Inscuteable) through the adapter protein Insc. Pins binds directly to Mud, which associates with the microtubule motor protein dynein, which moves toward microtubule minus-ends and generates pulling forces on the mitotic spindle. Upon phosphorylation by Aurora-A, Pins also binds to Dlg. Dlg in turn associates with Khc-73, a kinesin motor protein that moves toward and localizes at microtubule plus-ends, thus providing a microtubule-capture mechanism. (b) The Fz-Dsh complex regulates spindle orientation in *Drosophila* SOP through association with Mud, which binds to dynein.

suppressors. *Drosophila* neuroblasts with mutant *lgl*, *dlg*, and *scrib* fail to localize cell fate determinants correctly, and they generate daughter cells that divide and accumulate rapidly, leading to tumor development in larval imaginal discs and brains (Albertson and Doe, 2003). Currently, there is no definitive evidence that alteration of the mechanism of asymmetric division could be the cause of mammalian tumors. However, a strong correlation has been clearly described between changes (either downregulation or upregulation) in the normal expression pattern of polarity/junctional complexes and cancer. For example, mutations in the *CRB1* gene cause autosomal recessive retinitis pigmentosa (arRP) and autosomal Leber congenital amaurosis (arLCA). Several lines of evidence, obtained in both *Drosophila* and mice, show that loss of function of *Crb* or some of its intracellular interactors leads to morphological defects, loss of adhesion between photoreceptors, and light-induced degeneration of photoreceptor cells (Mehalow *et al.*, 2003), features comparable to those observed in patients lacking *CRB1* function (Den Hollander *et al.*, 2004). Furthermore, downregulation and loss of E-cadherin has been found in familial gastric cancers and breast cancers, respectively (Schrader *et al.*, 2008). Also, loss of α -catenin has been shown to increase cell proliferation,

decrease apoptosis, and suppress actin polymerization, which in turn decreases cell–cell adhesion (Benjamin and Nelson, 2008).

It should be added that cell proliferation and invasion have been correlated not only with loss of apical–basal polarity, but also with disruption of PCP signaling. Loss of the PCP protein Vangl 2 has been shown to promote migration and invasion of human cancer cells (Cantrell and Jessen, 2010). Polycystic kidney disease (PKD), a common genetic disorder in which abnormally growing fluid-filled cysts displace normal renal tubules, is a prime example of disease caused by defects in both planar and apical–basal polarity (Wilson, 2011).

Conclusions

- Cell polarity is responsible for orienting many cellular functions, such as cell shape, cell migration, and cell division.
- Conserved polarity complexes and common mechanisms generate and transduce cell polarity in both vertebrates and invertebrates.
- Epithelial cells display both apical–basal and planar polarity.

- Many of the genes controlling epithelial cell polarity regulate spindle orientation.
- Alterations of junctional and cell polarity complexes have been found to be associated with hyperproliferation and carcinogenesis.

Glossary

Autophagy (from the Greek *auto-*, 'self,' and *phagein*, 'to eat') The mechanism that involves intracellular degradation of unnecessary or dysfunctional cellular components through the formation of an isolation membranous compartment (the autophagosome) and its fusion with lysosomes.

Cytoskeleton A scaffold or skeleton that determines the shape of all cells. It forms structures such as flagella and cilia and plays a critical role in intracellular traffic, cell division, and cell migration. It is composed of three types of filaments: actin microfilaments, intermediate filaments, and microtubules. Phagocytosis strictly relies on the actin cytoskeleton as a force to deform the plasma membrane and on microtubules for the maturation of phagosomes into phagolysosomes.

Efferocytosis The process of internalization of dead cells or debris. It is mediated by recognition of ligands on the surface of the dead cell or debris by special receptors on the surface of the cells that will mediate ingestion. From *efferre*, Latin for 'to take to the grave,' 'to bury.'

Lysosomes Intracellular membrane-bound organelles of animal cells, where degradation of biomolecules occurs. They contain lytic enzymes that are active at an acidic pH.

Macropinocytosis A form of fluid-phase endocytosis allowing internalization of large volumes. It relies on actin- and PI3-kinase-dependent membrane ruffle formation that leads to the formation of intracellular macropinosomes. In immature DCs, macropinocytosis is constitutive and is down-regulated when DCs are mature. In other cells, macropinocytosis can be induced by growth factors, viruses, or bacteria.

Opsonization The coating of a particle with molecules, called opsonins, that renders it capable of being bound and ingested by phagocytic cells. Opsonins are host serum factors such as immunoglobulins and components of the complement cascade. From Greek, meaning 'to prepare a meal.'

Professional and nonprofessional phagocytic cells Some cells of the immune system are called professional phagocytes, as they perform phagocytosis very efficiently. They include dendritic cells, monocytes/macrophages, and polymorphonuclear neutrophils. Other cells might perform phagocytosis of cell debris, either occasionally or routinely (such as epithelial cells from the retina). The phagocytosis of cell debris has been called efferocytosis.

Introduction

Phagocytosis is a universal cell function, which starts with the recognition and binding of a particle (over 0.5 μm in diameter), generally in a receptor-dependent manner, and leads to its internalization and degradation. Single-celled eukaryotes such as the mold *Dictyostelium discoideum* and amoebae use phagocytosis for feeding. In higher organisms, phagocytosis is fundamental for host defense against invading pathogens and contributes to the immune and inflammatory responses

(Flannagan *et al.*, 2012; Swanson, 2008; Stuart and Ezekowitz, 2008). In mammals, phagocytosis is the hallmark of specialized cells including macrophages, dendritic cells, and polymorphonuclear neutrophils that can engulf large particles, microorganisms, and cell debris. These cells are collectively referred to as professional phagocytes. Phagocytosis is also important during development and in adulthood for normal turnover and remodeling of tissues and disposal of dead cells (Poon *et al.*, 2014). Indeed, epithelial cells from the retina are specialized in clearing fragments shed by photoreceptor

cells, which is important to enable normal vision. In addition, thyroid and bladder epithelial cells or mesangial cells in the kidney are able to perform phagocytosis. In this article, we will describe phagocytosis but not a related mechanism of internalization called macropinocytosis, which relies on related molecular mechanisms, but does not depend on surface receptors (Swanson, 2008).

Phagocytic Receptors

Many receptors on the surface of phagocytes participate to phagosome formation and maturation, although not all receptors are phagocytic per se, i.e., capable of mediating phagocytosis when expressed in non-phagocytic cells. Receptors on the surface of the phagocytes can be classified into two main classes: receptors for host serum factors (opsonins) such as immunoglobulin (Ig)G and the complement fragment C3b that engage Fc γ receptor (Fc γ Rs) and complement receptors (CR3, α M β 2), respectively, and non-opsonic receptors. The former are the archetypes of phagocytic receptors and have been best characterized. The latter include the Toll-like receptors (TLRs) and the non-TLRs such as lectins and scavenger receptors. They recognize components on the particle surface such as mannose or fucose residues, phosphatidylserine, and lipopolysaccharides (Aderem and Underhill, 1999; Underhill and Goodridge, 2012; Underhill and Ozinsky, 2002; Flannagan *et al.*, 2012; Canton *et al.*, 2013). Scavenger receptors were initially defined to characterize the uptake activity of receptors that recognized specifically oxidized low-density lipoproteins (Brown *et al.*, 1979; Canton *et al.*, 2013). A new nomenclature and classification has recently been proposed for scavenger receptors, which recognize altered molecules of the organism but also pathogen determinants (Prabhudas *et al.*, 2014).

Although recognition of a pathogen or cell debris involves binding to and clustering of several types of phagocytic receptors, the signaling events leading to actin polymerization and membrane deformation were essentially analyzed in experimental models that allow to trigger a single phagocytic receptor (Figure 1). For this, the Fc γ Rs or the two chains of the CR3 integrin receptor can be expressed in non-phagocytic cells, which confers them phagocytic properties per se, and allows

the signaling pathways to be dissected (Groves *et al.*, 2008). Another experimental approach to target a specific receptor is to coat or opsonize inert particles such as beads or red blood cells with a single ligand of interest. Zymosan, which is a heat-inactivated yeast, has also been used as opsonized particle to target Fc γ Rs or CR3, although direct binding of intrinsic yeast surface ligands to other phagocytic receptors like Dectin or mannose receptors cannot be excluded in this case.

Signaling to Actin Polymerization

Phagocytosis is strictly dependent on actin polymerization that will provide the force driving membrane deformation (Figure 2). Actin polymerization is intense and transient, and corresponds to the formation of a specific F-actin ring-like structure, called the phagocytic cup. Actin filaments experience a high turnover, with depolymerization at the base of the phagocytic cup and intense polymerization in the tips of the pseudopods. The actin ring diameter progressively shrinks until the two membrane extensions eventually fuse. This step probably involves a constriction activity generated by Myosin II, and possibly other myosins (Deschamps *et al.*, 2013; Swanson, 2008).

The signaling cascades leading to actin polymerization have been extensively studied. The signaling pathway leading to F-actin polymerization downstream of the Fc γ Rs will be described in detail, because it is considered as an archetype of the phagocytic receptors. Signaling requires receptor clustering, presumably via the binding to adjacent ligands on the surface of the target, in a zipper-like mechanism. Despite earlier suggestions to this effect, lipid microdomains do not seem to be implicated in the local concentration of receptors. It was recently described that receptors have two distinct mobilities in the plasma membrane: some diffuse freely and some are confined in fenestrated cortical actin structures that depend on the activity of Src-family and SYK kinases (Jaumouille *et al.*, 2014).

Upon receptor clustering, the tyrosines in the immunoreceptor tyrosine-based activation motif (ITAM) of the FcR or the associated gamma chain are phosphorylated by Src-family kinases, and serve as docking sites for Src homology 2 (SH2)

Figure 1 Experimental models of phagocytosis. (a) Beads, especially latex beads, have been extensively studied to induce phagocytosis, although the receptors triggered are not characterized; electrostatic interactions are thought to cluster unknown receptors. (b) and (c) Inert particles, such as beads, zymosan, or fresh red blood cells, can be opsonized with immunoglobulins to target the Fc receptors or with immunoglobulins and complement to target complement receptors such as CR3. (d) Zymosan is yeast inactivated by heat that exposes various pathogen molecular patterns recognized by receptors such as CR3, Dectin, Mannose receptors, and TLR.

Figure 2 Steps of phagosome formation. (a) Receptor clustering induces initial signaling and cup formation, with a wave of tyrosine phosphorylation, recruitment of adaptor proteins and other protein, and lipid kinases. Small GTPases lead to cascades of activation of actin NPF s and actin polymerization. (b) Pseudopod extension is characterized by further actin polymerization and remodeling at the base of the phagocytic cup, where depolymerization occurs. This is coordinated by membrane-associated phosphatases and allows focal delivery of intracellular compartments, under the control of the small GTPases of the Rab and ARF families. (c) Phagosome extension and closure. Further actin polymerization and membrane secretion, together with contractile activities are required for phagosome completion.

domain-containing cytosolic proteins. Among these are adaptors and scaffolding proteins such as Gab2, SLP-76, and CrkII. In particular, the tyrosine kinase Syk is recruited and in turn phosphorylates several substrates. The p85 subunit of type I phosphatidylinositol 3'-kinase (PI3K) is also recruited to ITAM sites, which allows a local accumulation of phosphatidylinositol 3,4,5-trisphosphate (PI(3,4,5)P₃), necessary to engulf large particles. Indeed, there is a dramatic change from a phase of phosphatidylinositol 4,5-bisphosphate (PI(4,5)P₂) accumulation that is predominant at the plasma membrane and necessary early to form the phagosome, to a phase of quick disappearance, just before phagosome scission (Botelho *et al.*, 2000). The loss of PI(4,5)P₂ leads to a rapid detachment of polymerized actin. Several enzymatic reactions might account for this disappearance and they will be discussed below in the section on actin dynamics.

Small guanosine 5'-triphosphatases (GTPases) of the Rho family are crucial regulators of actin polymerization. During FcγR phagocytosis, Cdc42 and Rac were identified as the key players and RhoG was more recently described to play a predominant role in phagocytosis triggered by other receptors, although this role has not been fully characterized (Caron and Hall, 1998; Cox *et al.*, 1997; Tzircotis *et al.*, 2011). Dynamic studies by fluorescence resonance energy transfer (FRET) revealed different patterns of activation for Rac and Cdc42. Active GTP-Cdc42 is present at the tip of the advancing pseudopod where it colocalizes with polymerizing actin, and Rac1 activation is biphasic. GTP-Rac1 is induced at a low level early after particle binding, and peaks at the time of pseudopod fusion (Hoppe and Swanson, 2004). Cdc42 activation and PI(4,5)P₂ accumulation in the nascent phagocytic cup activates effectors like N-WASP that is an actin nucleation-promoting factor (NPF). It acts on the actin related protein 2/3 (Arp2/3) actin nucleation complex, responsible for pseudopod extension. Rac1 is then essential for F-actin polymerization to complete extension and closure, through activation of another NPF, the WAVE complex. There might be a positive feedback loop leading to a transition from PI(4,5)P₂ and Cdc42 to PI(3,4,5)P₃ and Rac1 in which PI3K plays a role in PI(4,5)P₂ consumption and PI(3)P formation. Indeed, PI(3,4,5)P₃ represents a platform to recruit

other adaptor proteins and guanine nucleotide exchange factors (GEFs) that activate the small GTPases. The accumulated 3' phosphatidylinositols provide a negative feedback response to deactivate Cdc42 that allows actin disassembly necessary for phagosome closure (Beemiller *et al.*, 2010), while Rac1 and PI3K have been reported to signal in a positive feedback loop to sustain PI3K activity (Welch *et al.*, 2003).

Other Receptors and Signaling Pathways to Actin Polymerization

Various signaling pathways are induced downstream of surface phagocytic receptors, but they share signaling modules like kinases, small GTPases, and nucleation complexes. The signaling pathway induced by the CR3 has been studied in model systems using opsonized particles. This approach initially led to the description of two types of phagocytosis, type II being CR3-mediated phagocytosis. The CR3 integrins need an inside-out signal to reach an active conformation, bind their ligands, and become competent for uptake (Dupuy and Caron, 2008). The small GTPases RhoG and RhoA are critical for the signaling to actin polymerization. RhoA in turn activates effectors like the Rho-Kinase (ROK), the formin mDia1, and myosin II that are implicated in polymerization and contraction of F-actin around the particles (Caron and Hall, 1998; Colucci-Guyon *et al.*, 2005; Cox *et al.*, 1997; Olazabal *et al.*, 2002). The microtubules are important for this pathway and CLIP1 is especially required for efficient recruitment of mDia1 downstream of CR3 (Binker *et al.*, 2007; Lewkowicz *et al.*, 2008). The Dectin-1 (CLEC7A, SR-E2) receptor for β-glucans of bacterial and yeast cell walls and the Dectin-2 (CLEC6A) receptors for α-mannans also recently received a lot of attention. They contain ITAM motifs either in their cytosolic domain or in association with the Fcγ chain, which are important for the recruitment of SYK. Of note, phagocytosis of zymosan initiated by Dectin-1 is SYK independent (Kerrigan and Brown, 2010).

Finally the receptors involved in the uptake of cell debris or apoptotic cells induce a process recently termed 'efferocytosis'

(taken from *effero*, Latin for taking to the grave or to bury). Multiple receptors have been described and their redundancy or requirement in various environmental situations (tissue renewal and inflammation) is not well known. The combination of multiple low-affinity receptors provides an avidity that leads to engulfment. The externalization of phosphatidylserine (PtdSer) or its oxidized forms on apoptotic cells is recognized by a number of candidate receptors as well as groups of bridging molecules that bind to PtdSer and then to secondary receptors on the phagocytic cell. Among the former are T-cell immunoglobulin- and mucin domain-containing molecules (TIM1, TIM3, and TIM4), Stabilin-2, and RAGE (Receptor for advanced glycation end products). PtdSer-binding bridging molecules that include milk fat globule EGF 8 (MFG-E8), Protein S, and growth arrest-specific 6 (Gas6) are in turn recognized by phagocytic receptors such as $\alpha_v\beta_3$ integrins and the Tyro-Axl-Mer family (Korns *et al.*, 2011; Poon *et al.*, 2014; Canton *et al.*, 2013). Similar to PtdSer, externally exposed calreticulin is recognized by CD91 on the surface of phagocytic cells. Members of the scavenger receptor family formerly known as CD36 or CD68 have also been implicated in the uptake of apoptotic cells. In addition to these 'eat me' signals, apoptotic cells may dampen some inhibitory signals referred to as 'don't eat me' signals that normally prevent uptake by phagocytic cells (Poon *et al.*, 2014).

Signaling downstream of all these receptors is still a matter of debate and awaits detailed studies. As for other types of receptors, actin polymerization is crucial for efficient uptake. Engagement of efferocytic receptors initiates signaling events modulated by two main complexes, CrkII/ELMO/Dock180 or PTB domain-containing engulfment adaptor protein 1 (GULP), both resulting in activation of Rac1, which initiates cytoskeletal rearrangement and subsequent engulfment (Niedergang and Chavrier, 2005; Poon *et al.*, 2014). Since there are five mammalian DOCK180 family members and three ELMO isoforms, there may be finely tuned interplays between all these molecules, depending on the context and the cell function. Beside the positive regulation of engulfment by Rac1, a negative regulation of this pathway by Rho has been recently described in mammalian cells (Niedergang and Chavrier, 2005; Poon *et al.*, 2014).

Membrane Remodeling and Focal Exocytosis

Vesicular traffic is required for efficient phagosome formation in the case of large ($> 3 \mu\text{m}$) particles. The concept of membrane remodeling and 'focal delivery' of intracellular compartment at the site of phagocytosis emerged in the late 1990s (Hackam *et al.*, 1996, 1998). This was consistent with the observation that, instead of diminishing, the cell surface area increased upon phagocytosis (Hackam *et al.*, 1998; Holeyvinsky and Nelson, 1998). Evidence that focal exocytosis is required for optimal phagocytosis came from studies interfering with the fusion machinery composed of vesicle-soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors (v-SNAREs). Several intracellular compartments have been implicated in focal recruitment of fusion concomitant with phagosome formation, including recycling endosomes bearing VAMP3 on their surface (Bajno *et al.*, 2000; Niedergang *et al.*,

2003; Braun *et al.*, 2007) and late endocytic VAMP7⁺ compartments or lysosomes (Braun *et al.*, 2004; Czibener *et al.*, 2006). The events of compartment recruitment and fusion are regulated by small GTPases of the Rab and ARF family. Rab11, localized on the recycling compartments, is implicated in phagosome formation (Cox *et al.*, 2000; Damiani *et al.*, 2004; Patel and Harrison, 2008). ARF6 was shown to control the delivery of VAMP3 recycling endosomes, and Rab35 regulates actin-dependent phagosome formation by recruiting ACAP2, an ARF6 GTPase-activating protein (Egami *et al.*, 2011) or by regulating the localization of Rac1 and Cdc42 (Shim *et al.*, 2010). In addition, Rab11 and ARF6 activities are coordinated via common effectors like the Rab11-FIP3/4/RIP/RCP (Rab coupling proteins), also named arfophilins, or the exocyst complex. The exocyst complex is composed of eight subunits, among which Sec15, an effector of Rab11 and Sec10, an effector of ARF6, that is conserved from yeast to mammals and controls vesicle docking to the plasma membrane. The process of intracellular compartment recruitment and fusion plays a major role in phagosome formation by releasing tension for phagosome completion, but might also deliver specific cargoes or remodel the lipid composition. It has an additional role in the regulation of actin dynamics as explained in details below.

Linking Actin the Polymerization/Depolymerization Cycle with Vesicular Trafficking

Actin polymerization is strictly required for phagocytosis, but a high turnover of F-actin is also necessary for phagosome extension and closure. One way to generate actin turnover is supported by cofilin, which severs and depolymerizes F-actin filaments, and therefore provides G-actin subunits to support the rapid turnover-barbed end growth of filaments. Cofilin activity is negatively regulated by phosphorylation by the LIM kinase, which is activated by PAK, a direct effector of Rac1 and Cdc42. It was shown that Cdc42 inactivation and F-actin disappearance at the basis of the cup are directly correlated with and dependent on PI(4,5)P₂ hydrolysis (Scott *et al.*, 2005). During phagosome formation, several pathways contribute to the disappearance of PI(4,5)P₂. First, there is an arrest of its synthesis, due to the detachment of the phosphatidylinositol phosphate kinases (PIPKs) from the phagosome. Second, phospholipase C (PLC) γ hydrolyzes PI(4,5)P₂ into diacylglycerol and inositol-1,4,5-trisphosphate. Third, PI(4,5)P₂ is also phosphorylated and thereby consumed by class I PI3-kinases (PI3K) into PI(3,4,5)P₃. The PI(4,5)P₂ and PI(3,4,5)P₃ phosphatase oculocerebrorenal syndrome of Lowe (OCRL) has also been implicated in PI(4,5)P₂ hydrolysis and F-actin removal during phagocytosis in mammalian cells as in *Dicystostelium* (Marion *et al.*, 2012; Looovers *et al.*, 2007). OCRL is membrane-associated and recruited at the site of phagocytosis on AP1-positive compartments under the control of the NF- κ B signaling protein Bcl10 (Marion *et al.*, 2012; Deschamps *et al.*, 2013). As in other systems, the Rab5 and Rab35 GTPases could be also implicated in the recruitment of OCRL at sites of phagocytosis, and the Rab35/OCRL and the Rab11/FIP3 recycling pathways could act in parallel to restrict F-actin accumulation. The small GTP binding protein ARF6 is also a potent regulator of membrane trafficking and F-actin

remodeling (D'Souza-Schorey and Chavrier, 2006). ARF6 was shown to be activated during phagosome formation and to regulate efficient phagocytosis by controlling the focal delivery of intracellular components (Beemiller *et al.*, 2006; Niedergang *et al.*, 2003; Zhang *et al.*, 1998). Therefore, a complex interplay between intracellular compartments and signaling controls the actin dynamics and turnover that is required for vesicle exocytosis and further membrane extension and closure.

Maturation of Phagosomes into Phagolysosomes

Once sealed, the phagosome undergoes a series of fusion and fission events that lead to its progressive maturation into a phagolysosome compartment (Figure 3). The maturation process is accompanied by an acidification of the lumen and its migration on microtubules toward the cell center to reach a perinuclear localization. The early phagosome is similar to early endosomes, with the archetypal marker Rab5 and one of its effectors, the early endosome antigen 1 (EEA1). It has a pH of 6.1–6.5 and is poorly degradative. Effectors of Rab5A include EEA1, p150-hVPS34 complex, and SNARE proteins. The Ser and Thr kinase p150 allow the recruitment of hVPS34, a class III PI3K. The PI3P produced is recognized by proteins harboring a FYVE or PX domain, such as sorting nexins, Hrs, or p40phox. The products of PI3K are involved in the dissociation of Rab5 but are not essential for the recruitment of Rab7 on the phagosome (Vieira *et al.*, 2003). A critical step in phagosome maturation is the conversion from a Rab5

to a Rab7-positive compartment. The Rab5 effector identified as Mon1/SAND1, in a complex with Ccz1, acts as a GEF for Rab7 during endosome maturation and phagocytosis of apoptotic debris (Nordmann *et al.*, 2010; Kinchen and Ravichandran, 2010; Poteryaev *et al.*, 2010). The complex plays an important role in removing the Rabex5 GEF for Rab5 and attracting and activating Rab7 on phagosomes. The homotypic fusion and protein sorting (HOPS) complex, one of the many downstream regulators of Rab7 is implicated in phagosome maturation. The complex is composed of Vps11, Vps16, Vps18, Vps33, Vps39, and Vps41. The Vps41 protein, a key component of the HOPS complex, is required for the stabilization of the HOPS complex on the endosomal membrane prior to fusion with the vacuole in yeast. A key role and regulation by p38 MAPkinases of Vps41 has recently been highlighted to explain the differential traffic of virulent LPS of *Coxiella burnetii* (Barry *et al.*, 2012). Finally, emerging evidences suggest that maturation of phagosomes is also regulated by the recruitment of elements of the autophagy machinery, in particular the microtubule-associated protein 1 light chain 3 (LC3). Intersections of noncanonical autophagy and phagocytosis might have important roles in cell activation and antigen presentation (Mehta *et al.*, 2014; Romao and Munz, 2014).

The conversion from a Rab5- to a Rab7-positive compartment leads to a late phagosome with a more acidic pH of 5.5–6.0 due to acquisition of proton-pumping v-ATPases. The late phagosome is enriched in proteases and lysosomal-associated proteins (LAMPs). Various Rab7 effectors are then recruited to the late phagosome, including RILP and ORP1L, which act as adaptors for dynein (Harrison *et al.*, 2003; Johansson *et al.*,

Figure 3 Phagosome maturation. Once closed, the newly formed phagosome quickly loses the actin coat and modifies the lipid composition of its membrane. The phagosome then acquires characteristics of early endosomes and a mildly acidic lumen. A series of fusion and fission events with the endocytic compartments lead to the formation of a late phagosome with a more acidic lumen. Concomitantly, the phagosome moves along microtubules in a centripetal manner. Phagolysosomes, with an acidic pH guaranteeing the efficiency of acid hydrolases, concentrate around the nucleus, where the degradation of the ingested material occurs.

2007). This microtubule motor promotes the movement toward the minus end of microtubules and allows the centripetal movement of the phagosomes, as described in pioneering studies (Blocker *et al.*, 1997). The coordination between the microtubule-based movements and the fusion machinery is still not well defined, as well as the fate of the phagolysosomal products. Indeed, many studies were performed with nondegradable targets such as latex beads, and 'regurgitation' of the ingested material could be detected in that particular case. The biogenesis and homeostasis of lysosomes, as well as the signaling pathways associated to this organelle, are currently the subject of intense research, indicating that it represents much more than a garbage disposal step. There is no doubt that the same holds true for phagolysosomes.

Conclusion

Different types of phagocytosis stimulated by different receptors induce signaling cascades leading to relatively similar morphologic changes and the engulfment of particulate material. Several pathogens have evolved fine-tuned strategies to induce internalization processes in non-phagocytic cells, mimicking the phagocytic properties of professional phagocytes. In addition, later steps of phagocytosis are also hijacked by the intracellular microorganisms that shape the compartment in which they live to their advantage. These aspects will be developed in dedicated articles.

The signaling cascades triggered downstream of the surface receptors, however, induce various activation profiles of the cells leading to antigen presentation and more or less production of inflammatory cytokines. This important aspect will be the focus of further studies in the future to better understand and potentially manipulate the response of phagocytes that is crucial during the inflammatory response. Phagocytosis is indeed crucial at the onset of the inflammatory response to engulf pathogens. The resulting vascular changes and inflammatory mediators attract other leukocytes to the site of inflammation, in particular the short-lived neutrophils. These changes are normally transient and inflammation undergoes a resolution phase in which monocytes/macrophages play again a crucial role to clear the cell debris resulting from tissue damage and massive neutrophil death. Phagocytosis is therefore critical to control the resolution phase of inflammation. Recent evidence indicates that failure to induce efficient phagocytosis and clearance can lead to pathogen or debris persistence and chronic inflammatory responses responsible for widespread and debilitating human diseases such as atherosclerosis, multiple sclerosis, or type 2 diabetes (Tabas and Glass, 2013). Inefficient triggering of proinflammatory transcriptional responses, on the other hand, can favor the appearance of opportunistic infections. Targeting pathophysiological inflammatory processes without affecting vital immune responses is therefore an immense therapeutic challenge.

Macropinocytosis

Introduction

Pinocytosis was discovered and named by Warren Lewis, whose time-lapse movies of macrophages and cultured rat sarcoma cells revealed actively moving cell surface protrusions which folded back to enclose extracellular fluids into intracellular vesicles (Lewis, 1931; Lewis, 1937; Video 1). Smaller pinocytic vesicles discovered later by electron microscopy, initially called micropinosomes, were resolved into many different kinds of endocytotic activity: clathrin-coated vesicles, caveolae and uncoated small vesicles (Kumari *et al.*, 2010). Currently, endocytosis refers to all kinds of cellular ingestion. The term pinocytosis refers to fluid-phase endocytosis regardless of endocytic vesicle size. It will be used here to describe activities with undetermined contributions from macro- and micropinocytosis. Macropinocytosis is the process originally imaged by Lewis, the cellular ingestion of extracellular fluid into 0.2 μm or larger pinosomes derived from the plasma membrane.

Macropinosomes appear in cells after apparently chaotic movements of the cell cortex, often in response to acute stimulation by growth factors or other agents. Typically, actin-rich, petal-shaped extensions of plasma membrane, called ruffles, fold back against the cell surface or curve into circular ruffles that close at their distal margins to form intracellular vacuoles (Figure 1(a); Video 2). In some cultured cells that have been deprived of growth factor, the re-addition of growth factor stimulates cell spreading and the formation of two kinds of ruffle: peripheral ruffles and circular dorsal ruffles (CDR; Figure 1(b); Video 3) (Hoon *et al.*, 2012; Itoh and Hasegawa, 2013). Peripheral ruffles and CDR exhibit different dynamics and regulation, but are both capable of forming macropinosomes. CDR and the circular ruffles that form macropinosomes are sometimes considered equivalent structures.

However, the relationship of CDR to mechanisms of macropinosome formation under steady state conditions is not known.

Functions of Macropinocytosis

Although many cells exhibit macropinocytosis constitutively, it is an inducible process in other cells. Macropinocytosis is a common cellular response to stimulation by growth factors and may be important for growth factor receptor (GFR) signaling (Porat-Shliom *et al.*, 2008). Increased pinocytosis was observed after stimulation of amoebae or other cells with cationic molecules or nutrients (Chapman-Andresen, 1971), or of serum-starved cells with their cognate growth factors, including epidermal growth factor (Brunk *et al.*, 1976), platelet-derived growth factor (Davies and Ross, 1978), hepatocyte growth factor (Dowrick *et al.*, 1993), and macrophage-colony-stimulating factor (M-CSF) (Racoosin and Swanson, 1989). Stimulation of macropinocytosis has also been observed in response to cell-penetrating peptides (Nakase *et al.*, 2007), the tumor promoter phorbol myristate acetate (PMA) (Swanson, 1989), and lipopolysaccharide (Knight *et al.*, 1992).

Macropinocytosis contributes to physiology. Cells transformed by oncogenic K-Ras exhibit constitutively elevated macropinocytosis (Bar-Sagi and Feramisco, 1986), which internalizes sufficient protein to provide a source of amino acids for growth (Commisso *et al.*, 2013). This indicates that macropinocytosis provides an efficient route for the ingestion and degradation of solute nutrients in normal cells. In adaptive immunity, macropinocytosis by immature dendritic cells provides a mechanism for indiscriminate sampling of extracellular proteins for antigen processing and presentation by

Figure 1 Macropinocytosis and CDR formation in macrophages after stimulation with M-CSF. (a) Phase-contrast microscopic images at the indicated times after addition of M-CSF (min:sec), taken from Video 2. Arrows indicate stages of macropinosome formation: curved ruffle (8:00), circular ruffle (10:00), closed macropinosome (12:00), motile macropinosome (16:00 and 20:00). (b) Phase-contrast images of CDR, taken from Video 3. Arrows indicate the large continuous region of ruffling, which constricts to a smaller region of the cell before closing into several macropinosomes (15:20), which then fuse together and migrate centripetally (22:00). Scale bars = 10 μm .

MHC class I and MHC class II proteins. Constitutive macropinocytosis by immature dendritic cells internalizes extracellular proteins, followed by the partial degradation of proteins by lysosomal enzymes (Sallusto *et al.*, 1995). Upon maturation of dendritic cells, macropinocytosis decreases, with concomitant increases in recycling and presentation of antigen on cell surface MHC class II complexes. Moreover, leakage of internalized proteins from macropinosomes into the cytosol contributes to cross-presentation of exogenous antigen on dendritic cell MHC class I (Norbury *et al.*, 1995).

Although the term macropinocytosis refers to the engulfment of fluid and solutes, the movements of macropinocytosis have been implicated in various kinds of particle phagocytosis, including the cellular ingestion of bacteria, viruses, and apoptotic cells (Francis *et al.*, 1993; Hoffmann *et al.*, 2001; Mercer and Helenius, 2009). Macropinocytosis of low density lipoprotein by macrophages leads to cholesterol accumulation and foam cell formation in atherosclerotic plaques (Kruth, 2013). In neuronal cells, macropinocytosis is an essential part of growth cone collapse in repulsive axon guidance (Kolpak *et al.*, 2009).

Solute Flow During Pinocytosis

Lewis first suggested that pinocytosis provides a mechanism for cells to internalize and degrade extracellular solutes (Lewis, 1931). It was later shown that macrophages ingest proteins and carbohydrates via pinocytosis and degrade them in lysosomes (Cohn and Ehrenreich, 1969; Ehrenreich and Cohn, 1967). Electron microscopic studies of pinocytosis determined that the equivalent of the entire cell surface area in membrane is internalized several times per hour in *Acanthamoeba castellanii* (Bowers and Olszewski, 1972) and every 30 min in macrophages (Steinman *et al.*, 1976). This prompted studies which demonstrated considerable recycling of membrane and fluid-phase solutes during constitutive pinocytosis (Besterman *et al.*, 1981; Swanson *et al.*, 1985) and increased retention of internalized solutes when macropinocytosis was stimulated (Swanson, 1989).

In many cell types, macropinosomes interact to varying degrees with other endocytic organelles, including early endosomes, late endosomes, lysosomes and other macropinosomes (Amyere *et al.*, 2002; Kerr *et al.*, 2006; Racoosin and Swanson, 1993). The dynamics of organelle traffic following pinocytosis can lead to size fractionation of internalized solute molecules into distinct compartments (Berthiaume *et al.*, 1995). In some cells, however, macropinosomes recycle to the plasma membrane after minimal interactions with other organelles (Hewlett *et al.*, 1994).

Mechanisms of Macropinosome Formation

Actin dynamics and myosin-based contractility are necessary for ruffling and macropinosome closure. Many proteins implicated in the functioning of the actin cytoskeleton are required for macropinocytosis, including actinin-4 (Araki *et al.*, 2000), coronin (Grogan *et al.*, 1997) and myosins I, IIB, and V (Edgar and Bennett, 1997; Jiang *et al.*, 2010). The regulation of

the cytoskeleton for CDR formation has been extensively studied (Hoon *et al.*, 2012; Itoh and Hasegawa, 2013). Much of what is known there likely also applies to the regulation of the cytoskeleton for macropinocytosis.

GFR Signals that Affect Macropinosome Formation

Binding of growth factors to GFR initiates signal cascades which lead to cell growth. Many of those signals are also necessary for GFR-induced macropinocytosis. Growth factor binding leads to GFR dimerization, followed by activation of c-Src (Kasahara *et al.*, 2007) and Src-family kinases (SFK) (Metten *et al.*, 2006; Veracini *et al.*, 2006). v-Src-transformed fibroblasts exhibit high rates of macropinocytosis (Veithen *et al.*, 1996). SFK facilitate the recruitment of phospholipase C- γ 1 (PLC γ 1) (Veracini *et al.*, 2006) which hydrolyzes phosphatidylinositol (4,5)-bisphosphate (PtdIns(4,5)P₂) to diacylglycerol (DAG) and inositol trisphosphate (InsP₃). DAG activates protein kinase C, which is required for macropinosome formation (Miyata *et al.*, 1989).

Small GTPases

The movements of macropinocytosis are organized by small GTPases of the Ras superfamily. These proteins alternate between inactive, GDP-bound conformations and active, GTP-bound conformations. GTPases activate various effector proteins, primarily enzymes which regulate the actin cytoskeleton, membrane fusion and fission reactions or other GTPases. Guanine nucleotide exchange factors (GEFs) activate GTPases by accelerating the exchange of GTP for bound GDP. GTPase-activating proteins (GAPs) stimulate GTP hydrolysis and the return to inactive, GDP-bound conformations. GEFs and GAPs are often regulated by membrane phosphoinositides (PIs), which restrict the subcellular domains where GTPases may function (Bohdanowicz and Grinstein, 2013).

Ras

Although Ras is clearly important for macropinocytosis, the exact roles for Ras in macropinosome formation and trafficking remain poorly defined. Ras triggers ruffling through activation of Rac, and stimulates pinocytosis via Rab5 (Li *et al.*, 1997). Ras activates multiple effector proteins, including the p110 α catalytic subunit of type I phosphatidylinositol 3-kinase (PI3K) (Tamura *et al.*, 2009) and the Rab5 GEF Rin1 (Tall *et al.*, 2001), both of which are required for macropinosome formation. Ras remains active on macropinosome membranes, which serve as signaling platforms for growth stimulation (Porat-Shliom *et al.*, 2008; Welliver and Swanson, 2012).

Rac

Rac is required for nearly all kinds of macropinocytosis. Cells expressing constitutively active mutants of Rac exhibit increased ruffling and macropinosome formation (Ridley *et al.*, 1992). Rac is transiently activated in unsealed macropinocytic cups (Yoshida *et al.*, 2009), and experimental activation of Rac in sub-regions of cells induces localized ruffling and macropinosome formation (Fujii *et al.*, 2013). Rac effectors

implicated in macropinocytosis include Alsln/ALS2, which is a GEF for Rab5 (Otomo *et al.*, 2011), WAVE2, which stimulates actin polymerization (Sun *et al.*, 2003) and p21-activated kinase-1 (Pak1) (Dharmawardhane *et al.*, 1997; Dharmawardhane *et al.*, 2000). Pak1 phosphorylates and activates Ctb1/BARS, which mediates closure of the macropinosome and the activation of phospholipase D1 (PLD1) (Haga *et al.*, 2009; Liberali *et al.*, 2008). Significantly, Rac1 must be deactivated for complete macropinosome closure (Fujii *et al.*, 2013).

Rab5

Rab5 regulates macropinosome closure and subsequent trafficking. It localizes to macropinocytic cups prior to closure and persists on the macropinosome until it matures to a Rab7-positive organelle (Feliciano *et al.*, 2011; Porat-Shliom *et al.*, 2008; Welliver and Swanson, 2012). The Ras effector and Rab5 GEF Rin1 stimulates macropinocytosis (Balaji *et al.*, 2012). Rab5 effectors with roles in macropinocytosis include raban-kyrin-5 (Schnatwinkel *et al.*, 2004), Vps34 and EEA1 (Hamasaki *et al.*, 2004); these effectors regulate macropinosome closure or maturation. Together with Ras, Rac, and PI3K, Rab5 is necessary for CDR formation, likely by activating the Rab5 effector RNTre (Lanzetti *et al.*, 2004). Rab5 inhibition by overexpression of Rab GAPs destabilizes macropinosomes and promotes their recycling to the plasma membrane, indicating that a normal function of Rab5 is to facilitate closure or to prevent macropinosome recycling to the plasma membrane (Feliciano *et al.*, 2011). Rab5 may function on membranes of unclosed macropinocytic cups, as Rab5 activates OCRL and Inpp5B, which facilitate phagosome closure (Bohdanowicz *et al.*, 2012).

Other GTPases

Cdc42 regulates actin polymerization. It is active during macropinocytosis in dendritic cells (Garrett *et al.*, 2000) and mediates the macropinocytosis-like phagocytic engulfment of

Salmonella (Chen *et al.*, 1996). Active Arf6 stimulates actin polymerization and macropinocytosis (Porat-Shliom *et al.*, 2008; Schafer *et al.*, 2000). Other small GTPases implicated in macropinocytosis include RhoG (Ellerbroek *et al.*, 2004), Rab20 (Egami and Araki, 2012), Rab21 (Egami and Araki, 2009), and Rab34/Rah (Sun *et al.*, 2003).

Lipids

Phosphoinositides

The phosphoinositide (PI) phosphatidylinositol (PtdIns) and its phosphorylated relatives PtdIns3P, PtdIns4P, PtdIns5P, PtdIns(4,5)-bisphosphate (PtdIns(4,5)P₂), PtdIns(3,4)P₂, PtdIns(3,5)P₂, and phosphatidylinositol (3,4,5)-trisphosphate (PtdIns(3,4,5)P₃) are present in plasma membrane and the membranes of endocytic compartments (Bohdanowicz and Grinstein, 2013). PtdIns3P, PtdIns(4,5)P₂, PtdIns(3,4)P₂, and PtdIns(3,4,5)P₃ have been localized to macropinosomes and several PI kinases, phosphatases and lipases have been implicated in macropinosome formation or maturation (Hasegawa *et al.*, 2011; Maekawa *et al.*, 2014). PtdIns(3,4,5)P₃ appears transiently in circular ruffles (Yoshida *et al.*, 2009). PtdIns3P appears late during macropinosome closure and is required for macropinosome maturation (Araki *et al.*, 2006; Yoshida *et al.*, 2009; Figure 2; Video 4). In macrophages stimulated with M-CSF, PI3K inhibition does not alter ruffling or circular ruffle formation (ruffle closure), but instead inhibits a contractile activity that closes the macropinosome (cup closure) (Araki *et al.*, 1996; Swanson *et al.*, 1999).

Diacylglycerol

During constitutive macropinosome formation in v-Src-transformed fibroblasts, PLC functions after PI3K (Amyere *et al.*, 2000). The PI3K product PtdIns(3,4,5)P₃ activates PLC (Falasca *et al.*, 1998). The PLC product DAG and the DAG analog PMA stimulate pinocytosis (Keller, 1990; Swanson, 1989). DAG appears in macropinocytic cup membranes

Figure 2 The sequence of 3'PIs during macropinosome formation. The top and bottom sequences are aligned relative to the stages of macropinosome formation; hence, time (min:sec) is indicated relative to the first frame (rather than the time of M-CSF addition). Top: A time series showing macropinosome formation and a spike of PtdIns(3,4,5)P₃/PtdIns(3,4)P₂ (PIP₃) in a macropinocytic cup (taken from Video 4). A mouse macrophage expressing cyan fluorescent protein (CFP) and a yellow fluorescent protein (YFP)-labeled PH domain from Akt (YFP-AktPH), which binds to PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂, was imaged at 20-second intervals after stimulation with M-CSF. Corresponding phase-contrast and YFP/CFP ratio images are shown in a time series. A spike of PtdIns(3,4,5)P₃/PtdIns(3,4)P₂ (PIP₃) (2:40 to 4:00) appears after ruffle closure (2:00) and before cup closure (4:40). Bottom: A time series showing the generation of PtdIns3P during macropinosome formation. A macrophage expressing CFP and a YFP-2xFYVE chimera, which binds to PtdIns3P, was imaged at 20-second intervals after stimulation by M-CSF. PtdIns3P appears during or just after cup closure (4:40) and persists on the closed macropinosome. Color scale bars indicate relative YFP/CFP ratio values. Scale bars = 2 μm.

coincident with or shortly following the spike in PtdIns(3,4,5)P₃ (Welliver and Swanson, 2012).

Phosphatidic Acid

PLD, which synthesizes phosphatidic acid (PA) from phosphatidylcholine, is necessary for macropinosome formation in v-Src-transformed fibroblasts (Platek *et al.*, 2004). PA is required for macropinocytosis (Bohdanowicz *et al.*, 2013) and may function indirectly by activating the PtdIns(4,5)P₂-synthesizing enzyme PtdIns-4-phosphate-5-kinase (Honda *et al.*, 1999) or by recruiting the Rac1 GEF DOCK1 to plasma membrane (Sanematsu *et al.*, 2013).

Cholesterol

Although the role for cholesterol in macropinosome formation is not known, methods which deplete cellular cholesterol inhibit macropinocytosis (Grimmer *et al.*, 2002).

Other Necessary Molecules

Dynamin

Dynamin facilitates scission of clathrin-coated pits into coated vesicles (Schmid and Frolov, 2011). Its contribution to macropinocytosis is unsettled. Inhibition of dynamin 2 function inhibits macropinosome formation (Liu *et al.*, 2008). However, Cao *et al.*, found that dynamin was not required for macropinocytosis (Cao *et al.*, 2007). Dynamin 2 interacts with cortactin and Arp2/3 in the formation of CDR (Krueger *et al.*, 2003).

SNX proteins

The nascent macropinosome transforms from an irregular profile to a more rounded morphology with thin tubulovesicular extensions radiating along cytoplasmic microtubules. These extensions are formed by SNX-family proteins, which are regulated by PtdIns3P or PtdIns(3,4)P₂. The morphological changes may increase hydrostatic pressure inside the macropinosome (Kerr *et al.*, 2006). SNX1, 5, 9, 18, and 33 affect macropinosome formation or maturation (Lim *et al.*, 2012; Wang *et al.*, 2010).

Microtubules

Microtubule-depolymerizing drugs inhibit macropinocytosis by unknown mechanisms (Racoosin and Swanson, 1992; Swanson *et al.*, 1987). Conversely, microtubule destabilization promotes macropinosome formation. Histone deacetylase-6 (HDAC6) removes acetyl groups from tubulin in microtubules, leading to microtubule destabilization. HDAC6 localizes to ruffles and macropinosomes and stimulates macropinocytosis (Gao *et al.*, 2007). Moreover, a *Shigella* effector protein stimulates macropinocytosis for bacteria entry into host cells using an effector protein which destabilizes microtubules (Yoshida *et al.*, 2002). This suggests that dynamic microtubules are required for macropinosome formation.

The Organization of Cytoplasm for Macropinosome Formation

The movements of macropinosome formation and maturation are coordinated by interrelated networks of PIs, GTPases, GEFs, GAPs, and effector proteins which appear at distinct stages of macropinosome formation. A cascade of chemical reactions begins shortly after cell surface ruffles become circular ruffles (a.k.a. ruffle closure) (Maekawa *et al.*, 2014; Yoshida *et al.*, 2009). A spike of PtdIns(4,5)P₂ is followed by transient peaks of several signals, including PtdIns(3,4,5)P₃, Rac1 and DAG, which are terminated before the cup closes into a macropinosome. This is followed by a transient spike in PtdIns(3,4)P₂, which coincides with cup closure, then a slower peak comprised of PtdIns3P, Rab5a, Ras, and PKC α (Welliver and Swanson, 2012). This sequence of signals occurs during the formation of each macropinosome, and at different times after growth factor stimulation, which suggests that signaling is a self-organized cascade of chemical reactions guided by cell surface structure. Lateral diffusion of fluorescent proteins tethered to the inner leaflet of macrophage plasma membrane is restricted to macropinocytic cups following ruffle closure and prior to scission of the macropinosome from plasma membrane into a discrete intracellular vacuole (a.k.a. cup closure) (Welliver *et al.*, 2011). Restricted diffusion in subdomains of plasma membrane may facilitate signal amplification and the signal transitions necessary for macropinosome formation.

Experimental Diagnosis

Morphology

The clearest diagnostic method for detecting macropinocytosis is to observe macropinosomes directly. Time-lapse, light microscopy can show macropinosome formation in regions of cell surface ruffling or blebbing (Figure 1(a); Video 2). Alternatively, macropinosomes can be fluorescently labeled by brief, 3- to 15-minute incubation in medium containing a fluid-phase tracer, followed by brief rinsing in unlabeled medium, fixation and observation by light and fluorescence microscopy. Large, phase-bright, fluorescent macropinosomes can be counted directly (Commisso *et al.*, 2014). Fluorescein dextran (Fdx) and Lucifer yellow are nearly ideal fluorescent probes, as they do not adsorb to cell surfaces or induce endocytosis, and remain undegraded and membrane-impermeant for some time after uptake (Berthiaume *et al.*, 1995; Swanson *et al.*, 1985). Larger macromolecules enter macropinosomes more efficiently than smaller endocytic vesicles (Araki *et al.*, 1996; Berthiaume *et al.*, 1995); thus, high molecular weight Fdx (e.g., avg. mol. wt. 70 000) can be used to bias endocytic compartment labeling for macropinosomes.

Actin and Myosin

Agents which selectively inhibit actin polymerization, depolymerization, or the contractile activities of myosin, can inhibit macropinocytosis. Cytochalasin D and E, which inhibit actin filament turnover (Cooper, 1987), latrunculin A or B,

which depolymerize actin filaments (Coue *et al.*, 1987) and jasplakinolide, which inhibits actin depolymerization (Bubb *et al.*, 1994), all inhibit macropinocytosis. Macropinocytosis is also inhibited by the myosin light chain kinase inhibitor ML-7 (Araki *et al.*, 2003) and by the myosin II inhibitor blebbistatin (Jiang *et al.*, 2010; Shu *et al.*, 2005).

Amiloride

The sodium/proton antiport inhibitor amiloride and the related compounds ethyl isopropyl amiloride (EIPA) and HOE-694 inhibit macropinocytosis selectively (Koivusalo *et al.*, 2010; West *et al.*, 1989). They lower cytoplasmic pH near the plasma membrane; consequently inhibiting membrane-proximal cytoskeletal regulatory proteins (Koivusalo *et al.*, 2010). The inhibition of endocytosis by amiloride remains the most common diagnostic test for macropinocytosis.

Other Inhibitors

Additional inhibitors of macropinocytosis include wortmannin and LY294002 (Araki *et al.*, 1996), which inhibit PI 3-kinase, and rottlerin (Sarkar *et al.*, 2005), which works through unknown mechanisms. The PI 3-kinase inhibitor 3-methyladenine does not prevent macropinosome formation, but inhibits macropinosome maturation (Araki *et al.*, 2006).

Macropinocytosis and related engulfment activities have been indirectly linked with metabolic regulation. Uptake of Flock House virus by macropinocytosis requires AMP kinase, whose activity is regulated by cellular energy levels (Konradtowitz *et al.*, 2013). Macropinocytosis can be inhibited by rapamycin (Hackstein *et al.*, 2002), an inhibitor of the metabolic regulatory protein mTOR.

Dysregulation

Cancer

Oncogenic K-Ras, H-Ras, v-Src, and Abi1 all increase rates of macropinocytosis (Bar-Sagi and Feramisco, 1986; Dubielecka *et al.*, 2010; Veithen *et al.*, 1996). Unregulated macropinocytosis may contribute to unrestrained growth of tumor cells (Commisso *et al.*, 2013).

Bacterial Invasion

Various pathogenic bacteria are engulfed by host cells, including otherwise non-phagocytic cells, by triggering macropinocytosis. This was first described for *Salmonella Typhi* var. Typhimurium (Alpuche-Aranda *et al.*, 1994; Francis *et al.*, 1993) and later observed for *Legionella pneumophila* (Watarai *et al.*, 2001), *Brucella abortus* (Watarai *et al.*, 2002), *Neisseria gonorrhoeae* (Zenni *et al.*, 2000), and *Shigella flexneri* (Ogawa *et al.*, 2008).

Virus Infection

Eukaryotic cells internalize viruses by different routes, including clathrin-mediated endocytosis, caveolin-mediated endocytosis and macropinocytosis (Mercer *et al.*, 2010).

Vaccinia virus infects by triggering macropinocytosis (Mercer and Helenius, 2008). Other viruses which infect via macropinocytosis include echovirus 1 (Krieger *et al.*, 2013), adenovirus (Amstutz *et al.*, 2008), Flock House virus (Nakase *et al.*, 2009), Ebola virus (Saeed *et al.*, 2010), and HIV-1 (Liu *et al.*, 2002; Marechal *et al.*, 2001).

Therapeutics

Drug Delivery

Cell-penetrating peptides and cationic liposomes have been developed for therapeutic delivery of macromolecules into the cytoplasm. Many of these delivery vehicles enter cytoplasm from inside macropinosomes (Cardarelli *et al.*, 2012; Nakase *et al.*, 2007).

Cancer

Methods and reagents for manipulating macropinocytosis may find use as anti-cancer therapies. Stimulation of macropinocytosis in neuroblastoma cells by transfection with Ras or Rac causes an unusual form of cell death called methuosis, in which macropinosomes form, enlarge and rupture (Maltese and Overmeyer, 2014; Overmeyer *et al.*, 2008). Stimulation of methuosis may provide a therapeutic strategy for selectively killing these cells (Kitambi *et al.*, 2014).

Glossary

Apoptosis A noninflammatory form of programmed cell death.

Inflammasome One of several multiprotein complexes in the macrophage cytosol that contain caspase-1 and are required for secretion of proinflammatory cytokines such as IL-1 β .

Inflammation A rapid response to infection that is driven by macrophage cytokines and is characterized by tissue swelling, heat, redness, and pain.

NADPH oxidase An enzyme complex in phagocytes that is essential for host defense and catalyzes the conversion of oxygen into superoxide anions.

Neutrophil extracellular traps (NETs) NETs are networks of DNA, histones, and granule proteins released by activated neutrophils that can ensnare extracellular microbes.

Pathogen The subset of all microorganisms that have the capacity to cause disease.

Phagocytosis A receptor- and actin-driven endocytic process that allows macrophages, neutrophils, and dendritic cells to ingest whole bacteria and fungi.

Phagosome maturation The process of converting a nascent phagosome into a lysosome-like compartment for optimal microbe killing.

Pyroptosis A proinflammatory form of macrophage death that is triggered by inflammasome activation.

ROS Reactive oxygen species include superoxide anions, hydrogen peroxide, hypochlorous acid, and other toxic oxygen radicals and derivatives that are critical for host defense.

Phagocytes and Phagocytosis

Phagocytes are certain types of white blood cells (leukocytes) that are unique in their ability to bind and engulf large particles such as bacteria, fungi, and parasites. The term phagocyte means 'cells that can eat,' and the two main types of phagocytes are macrophages and neutrophils. Small numbers of macrophages are present in all body tissues. In contrast, neutrophils, which are also called polymorphonuclear leukocytes, reside in the bloodstream and are rapidly recruited from this locale to sites of infection or tissue damage. Phagocytes and the process of phagocytosis were originally described by Elie Metchnikoff in the late nineteenth century, and these early studies also revealed unique morphological features of neutrophils such as their lobed nuclei and abundant cytoplasmic granules (reprinted in [Cavaillon, 2011](#)).

Mechanisms of Phagocytosis

Phagocytosis is a specialized type of endocytosis that is unique to phagocytes. At the molecular level, phagocytosis is defined as a receptor-mediated and F-actin-dependent mechanism for internalization of particles that are at least 0.5 μm in diameter ([Figure 1](#)). There are many receptors on macrophages and neutrophils that mediate phagocytosis ([Freeman and Grinstein, 2014](#)). Some of these receptors bind directly to microbe surface proteins or carbohydrates, and examples of receptors in this class are the macrophage mannose receptor, dectin-1, and scavenger receptors. Other receptors that mediate phagocytosis bind indirectly to microbes that have been pre-coated with molecules termed opsonins that enhance their ability to be engulfed. The process of coating microbes with opsonins is called opsonization, which means 'to prepare for eating.' The two major types of opsonins are antibodies of the

IgG class, and complement proteins C3b and C3bi. Receptors that bind microbes coated with IgG are called Fc γ receptors and include CD16, CD32, and CD64. The receptor that binds C3b is called complement receptor 1 (CR1, also called CD35), whereas both CR3 (also called CD11b/CD18, $\alpha_M\beta_2$ or Mac-1) and CR4 (CD11c/CD18, $\alpha_X\beta_2$) bind particles that have been opsonized with C3bi. In many instances, multiple receptors can participate in uptake of a given microorganism. However, to study the properties of individual receptors in isolation, research studies often use latex beads or other particles that

Figure 1 Receptors for phagocytosis. Phagocytosis of microbes is a receptor-dependent endocytic process that allows macrophages and neutrophils to ingest bacteria, fungi, and parasites. Some phagocytic receptors, such as the mannose receptor or scavenger receptors, bind directly to sugars, proteins, or other molecules on microbe surfaces. On the other hand, Fc γ receptors and complement receptor 3 (also called CR3, Mac-1, $\alpha_M\beta_2$) bind indirectly to microbes that have been opsonized (pre-coated) with IgG and C3bi, respectively. Regardless of the receptor engaged, extension of the plasma membrane around the microbe also requires local polymerization of actin filaments (F-actin).

are coated with ligands for individual receptor types, such as IgG.

Many of the fundamental principles of phagocytosis were defined by Silverstein and colleagues in the 1970s (Griffin *et al.*, 1975). These studies demonstrated that ligands for phagocytic receptors must be present over the entire surface of the microbe or particle being engulfed, since hemispherically opsonized targets were only partially ingested. They also showed that local actin polymerization provides the driving force for plasma membrane extension. Moreover, microbe binding and uptake could be distinguished, as binding was intact when phagocytes were incubated at 4 °C or in the presence of drugs that blocked actin polymerization, yet engulfment did not occur.

Subsequent studies have shown that many actin-binding proteins, guanosine triphosphatases (GTPases) and protein and lipid kinases are also recruited to forming phagosomes (Aderem and Underhill, 1999; Freeman and Grinstein, 2014). These molecules provide additional essential signals that regulate phagocytosis and also modulate the morphology of forming phagosomes. Thus, in some instances, phagocytes appear to reach out and grab their prey using long pseudopodia, whereas in other instances, the particles appear to sink into the cell surface (Allen and Aderem, 1996). Regardless of the specific receptor engaged, it is also noteworthy that macrophage surface area increases during phagocytosis, a finding which suggested a mechanism for plasma membrane expansion during particle engulfment that was confirmed by measurements of membrane capacitance (Holevinsky and Nelson, 1998). The results of additional studies indicate that multiple intracellular membrane compartments can be mobilized and contribute to this process, but as yet no one compartment or type of vesicle appears to be essential.

Phagocytic Killing

Central to effective immunity and host defense is the ability of phagocytes to rapidly and efficiently kill the microbes that they ingest. To achieve this, a multifaceted approach is utilized that includes production of toxic reactive oxygen species (ROS), sequestration of critical nutrients, and exposure to numerous hydrolytic enzymes and cationic peptides that directly damage and degrade microbes and microbe components. The efficiency of this process is enhanced by the phagosome itself, which allows the components of the killing arsenal to be concentrated in close proximity to the ingested microbe. The mechanisms that contribute to phagocytic killing are described here along with the associated process of phagosome maturation.

Oxygen-Dependent Killing

In general, the processes that contribute to phagocytic killing can be divided into two groups, those that require oxygen and those that do not. Three enzymes that are critical for oxidative host defense are the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex, myeloperoxidase (MPO), and inducible nitric oxide synthase (iNOS).

NADPH oxidase and MPO

The central player in oxidative host defense is the phagocyte NADPH oxidase (*phox*) complex which catalyzes the conversion of molecular oxygen into superoxide anions. Because toxic oxidants can damage host tissue as well as microbes, the activity of this enzyme is under tight spatial and temporal control. The enzyme itself consists of six subunits (Nauseef, 2004; DeLeo and Quinn, 1996). Two integral membrane components gp91^{phox} (also called Nox2) and p22^{phox} form a heterodimer called flavocytochrome b₅₅₈ that contains the catalytic core of the enzyme and localizes to the plasma membrane and early endosomes of macrophages, and the plasma membrane, specific granules and gelatinase granules of neutrophils (DeLeo and Quinn, 1996; Casbon *et al.*, 2009). The four other subunits are p47^{phox}, p67^{phox}, p40^{phox}, and the GTPase Rac, all of which are soluble proteins distributed throughout the cytosol.

In resting (unstimulated) phagocytes the NADPH oxidase complex is unassembled and inactive, with subunits segregated in different subcellular compartments (Figure 2). However, within 30 s of microbe binding flavocytochrome b₅₅₈ is recruited to forming phagosomes from the plasma membrane and intracellular stores, and becomes highly enriched in this locale (Allen *et al.*, 1999). Simultaneously, protein kinase C (PKC) phosphorylates multiple serine residues of p47^{phox} which triggers *en bloc* membrane translocation of p47^{phox}/p67^{phox}/p40^{phox} complexes, whereas active Rac translocates to the membrane independently (Allen *et al.*, 1999; DeLeo *et al.*, 1999; DeLeo and Quinn, 1996; Nauseef, 2004). The assembled, active NADPH oxidase complex catalyzes the conversion of molecular oxygen into superoxide anions, which accumulate in the phagosome lumen. Because large amounts of oxygen are consumed in this process, NADPH oxidase activation is often referred to as 'the respiratory burst.' Nonetheless, superoxide itself is only moderately toxic. Microbe killing is therefore enhanced by rapid dismutation of superoxide into hydrogen peroxide (H₂O₂). Moreover, neutrophils also contain MPO, an enzyme that catalyzes the conversion of H₂O₂ into highly toxic hypochlorous acid (HOCl), which kills microbes by chlorination of proteins, lipids, and DNA, and notably is also the active component of chlorine bleach (Klebanoff *et al.*, 2013; Schwartz *et al.*, 2009). Thus, in neutrophils the NADPH oxidase complex and MPO act in concert to generate microbicidal ROS during the first 60–90 min after phagocytosis (DeLeo *et al.*, 1999). Although the signals that terminate the respiratory burst in macrophages and neutrophils are not well defined, it is established that this process is accompanied by NADPH oxidase disassembly, as indicated by reverse translocation of Rac, p47^{phox}, p67^{phox}, and p40^{phox} from the phagosome membrane to the cytosol (DeLeo *et al.*, 1999; McCaffrey *et al.*, 2010).

iNOS

Although macrophages do not express MPO, they can be induced to express another enzyme that also has the capacity to increase the toxicity of superoxide anions, iNOS (also called NOS2). Specifically, iNOS expression is upregulated in macrophages exposed to certain bacterial products or proinflammatory cytokines such as lipopolysaccharide (LPS) or

Figure 2 Oxidative host defense mechanisms. The phagocyte NADPH oxidase complex is comprised of six subunits: an integral membrane heterodimer (gp91^{phox}/p22^{phox}), and four soluble subunits (p47^{phox}, p67^{phox}, p40^{phox}, and Rac). This enzyme is disassembled in cells at rest, but is rapidly activated during phagocytosis. To this end, specific granules deliver gp91^{phox}/p22^{phox} to forming phagosomes. Simultaneously, phosphorylation of p47^{phox} and other signals trigger membrane translocation of the soluble subunits. The assembled, active enzyme catalyzes the conversion of molecular oxygen into superoxide anions, which then dismutate to form H₂O₂. Neutrophil phagosomes also acquire MPO from azurophilic granules. MPO catalyzes the conversion of H₂O₂ into HOCl, which is highly toxic to microbes and is also the active component of chlorine bleach.

interferon- γ , respectively (MacMicking *et al.*, 1997). iNOS catalyzes the conversion of L-arginine and oxygen into NO and citrulline, and highly toxic peroxynitrite (ONOO⁻) is generated when NO reacts with superoxide (MacMicking *et al.*, 1997). Although it is firmly established that iNOS is important for microbe killing by rodent macrophages, the contribution of this enzyme to the defense repertoire of human macrophages remains controversial, and the results of recent studies indicate that the iNOS promoter is silenced in alveolar macrophages isolated from human lungs (Gross *et al.*, 2014).

Chronic granulomatous disease

The importance of the respiratory burst and ROS in antimicrobial host defense is exemplified by the phenotype of persons with chronic granulomatous disease (CGD) (Matute *et al.*, 2009; Curnutte, 1993). Persons with CGD suffer from repeated, life-threatening bacterial and fungal infections due to inherited mutations in any one of the genes that encode NADPH oxidase subunits. Notably, CGD macrophages and neutrophils exhibit normal phagocytosis and oxygen-independent killing capacity (Allen *et al.*, 1999), and because of this persons with CGD are not uniformly susceptible to all infections. Rather, they are particularly susceptible to infection with bacteria such as *Staphylococcus aureus* and *Burkholderia cepacia*, and fungi such as *Aspergillus fumigatus* (Ben-Ari *et al.*, 2012). This illustrates the fact that each bacterial and fungal species exhibits differential sensitivity to the individual host defense mechanisms – including ROS – that are deployed by phagocytes.

Phagosome Maturation

Phagosome maturation is the process of converting a nascent phagosome into a degradative, lysosome-like compartment called a phagolysosome. Phagosome maturation has been extensively studied, and it is now clear that this process ensues

rapidly after microbe binding or uptake. However, both the kinetics of this process and the underlying molecular events differ significantly in macrophages and neutrophils, and this reflects the fact that neutrophils are granulocytes whereas macrophages are not. Thus, phagosome maturation in macrophages is a relatively slow process that involves incremental modification of phagosome composition over an hour or more via sequential interactions of this compartment with organelles of the endosomal pathway (Figure 3). In contrast, phagosome maturation in neutrophils is extremely rapid and is mediated by fusion of three types of cytoplasmic granules with forming and nascent phagosomes (Figure 4). Despite differences in the underlying molecular mechanisms, mature phagosomes in both phagocyte types are optimized for microbe killing and degradation.

Macrophage phagosome maturation

Until the mid-1980s it was generally believed that phagosome maturation was achieved by direct fusion of lysosomes with nascent phagosomes (Steinman *et al.*, 1983). This view began to change with the realization that remodeling of the phagosome membrane was rapid, and that most plasma membrane proteins disappeared from these structures within minutes of uptake (Muller *et al.*, 1980). Additional studies revealed that phagosomes become progressively acidified due to the action of an enzyme called the vacuolar proton adenosine triphosphatase (V-ATPase) that accumulates in phagosome membranes as they mature and pumps protons into the phagosome lumen (Mellman *et al.*, 1986).

Shortly thereafter, two research groups provided the first direct evidence to indicate that phagosome-endosome fusion occurs in macrophages and precedes phagosome fusion with lysosomes (Hart and Young, 1991; Mayorga *et al.*, 1991). Hart and Young examined phagosome composition using electron microscopy and central to their success was the use of macrophages that had been pretreated with ammonium

Figure 3 Macrophage phagosome maturation. The composition of nascent phagosomes in macrophages is modified incrementally by sequential interactions with early endosomes, late endosomes, *trans*-Golgi network-derived vesicles, and lysosomes. Prominent markers of early, late, and mature phagosomes include: Rab5 and EEA1; Rab7, LBPA, immature cathepsins and lamp-1; and mature cathepsins and lamp-1, respectively. Collectively, this process is called phagosome maturation, and it culminates in generation of an acidic compartment called a phagolysosome. The low pH and abundant hydrolases in mature phagolysosomes are critical components of the oxygen-independent killing arsenal of macrophages. EEA1, early endosome antigen-1; LBPA, lysobisphosphatidic acid; lamp-1, late endosome/lysosome-associated membrane protein-1.

Figure 4 Neutrophil phagosome maturation. Maturation of neutrophil phagosomes is extremely rapid. Thus, fusion of all three types of cytoplasmic granules with forming phagosome begins within seconds of microbe binding and is apparent even before uptake and phagosome sealing is complete. Host defense components delivered into phagosomes by each granule population are listed. MPO, myeloperoxidase; BPI, bacteriocidal permeability-increasing protein.

chloride (NH₄Cl), which accumulates inside acidic membrane compartments (such as lysosomes) and neutralizes their pH. Under these conditions phagosome-lysosome fusion is blocked, and this allows phagosomes with endosome-like characteristics to accumulate (Hart and Young, 1991). The Stahl group also provided direct evidence of phagosome-endosome fusion in intact cells and were the first to reconstitute this process *in vitro*, thereby defining requirements for GTP and *N*-ethylmaleimide-sensitive factors in this process

(Mayorga *et al.*, 1991). Biochemical analyses of phagosomes isolated from macrophages at several time points during the first 20 min or so after particle uptake confirmed the rapid disappearance of phagocytic receptors and other plasma membrane proteins from these structures, as well as progressive accumulation of V-ATPase, and also demonstrated that phagosome acquisition of late endosome markers – such as the mannose-6-phosphate receptor (M6PR) – preceded acquisition of lysosomal enzymes such as cathepsin D (Pitt *et al.*, 1992). Collectively, the results of these pioneering studies provided a framework for in-depth studies of the underlying mechanisms.

Today, it is firmly established that maturation of macrophage phagosomes is intimately linked to membrane trafficking in the endosomal pathway, and as such phagosome composition is dynamic and changes rapidly during the first 5–60 min after microbe uptake via sequential interactions with early endosomes, late endosomes, vesicles derived from the *trans*-Golgi network, and lysosomes (Figure 3). Current understanding of this process has been informed by in depth analyses of phagosome protein and lipid composition, together with immunofluorescence and confocal microscopy and the development of probes for live cell imaging (Garin *et al.*, 2001; Russell *et al.*, 2009; Botelho *et al.*, 2000; Henry *et al.*, 2004; Vieira *et al.*, 2001).

Although our understanding of the molecular mechanisms is incomplete, several points of regulation have been identified, including a role for Rab family GTPases. Humans express more than 60 Rab GTPases, each of which has a distinct subcellular localization and regulates specific membrane trafficking and fusion events (Stenmark, 2009). Among these,

Rab5 and Rab7 are critical for phagosome maturation (Aderem and Underhill, 1999; Farin and Grinstein, 2012). Rab5 is a marker of early endosomes and mediates fusion of nascent phagosomes with these compartments. Consequently, in the first few minutes after sealing, early phagosomes are enriched for Rab5 and its effectors early endosome antigen-1 (EEA1) and the class 3 phosphatidylinositol 3-kinase Vps34, as well as other early endosome markers such as transferrin receptor. Subsequent disappearance of Rab5 and other early markers is accompanied by the appearance of late endosome markers on maturing phagosomes, including Rab7, late endosome/lysosome-associated membrane protein-1 (lamp-1), lamp-2, CD63, and lysobisphosphatidic acid (LBPA) (Henry *et al.*, 2004; Farin and Grinstein, 2012; Aderem and Underhill, 1999; Figure 3). Rab5-to-Rab7 conversion is essential for phagosome maturation, and this is due in part to the fact that Rab7 effectors including Rab-interacting lysosomal protein promote interactions of late phagosomes with microtubules and the dynein-driven movement of these compartments to the lysosome-rich perinuclear area (Farin and Grinstein, 2012; Harrison *et al.*, 2003). Late phagosomes also contain newly synthesized, immature hydrolases such as cathepsin D, which are delivered to phagosomes and late endosomes from the *trans*-Golgi network by M6PRs, which then recycle back to the Golgi via a Rab9-dependent mechanism (Vieira *et al.*, 2002; Stenmark, 2009). Thus, aberrant expression, targeting, or activity of Rab5, Rab7, Rab9, or Vps34 impairs phagosome maturation (Stenmark, 2009; Farin and Grinstein, 2012). Phagolysosomes are distinguished from late phagosomes by their greater density of lamp-1, lamp-2, and V-ATPase and lower pH, as well as their lack of LBPA and M6PRs and their enrichment for mature cathepsin D (Figure 3; Vieira *et al.*, 2002). Of note, more recent studies have identified roles for several additional Rab GTPases in regulation of phagosome acidification and maturation including Rab20, Rab22b, Rab32, Rab34, Rab38, Rab39, and Rab43 (Seto *et al.*, 2011).

Additional regulators of phagosome maturation include calcium/calmodulin and the alpha isoform of PKC (PKC α) (Allen and Aderem, 1995; Holm *et al.*, 2003; Vergne *et al.*, 2003). Several PKC isoforms are expressed in macrophages and contribute to phagocytosis, NADPH oxidase activation, and phagosome maturation in an isoform- and particle-dependent manner (Allen and Aderem, 1995; Larsen *et al.*, 2000; Allen and Allgood, 2002). PKC α differs from the other phagosome markers discussed above as it accumulates on forming phagocytic cups within seconds of microbe or particle binding, yet is retained throughout the maturation process and is essential for phagosome-lysosome fusion (Allen and Aderem, 1995; Holm *et al.*, 2003). Consistent with this, phagosomes also accumulate PKC substrates and molecules that modulate PKC α activation, including diacylglycerol and phosphatidylserine (Allen and Aderem, 1995; Levin *et al.*, 2015).

Neutrophil phagosome maturation

Phagosome maturation occurs by a different mechanism in neutrophils, and this reflects the distinct structure of this cell type as a granulocyte (Figure 4). Three types of granules are synthesized during neutrophil development in the bone

marrow: azurophilic (primary) granules (AG), specific (secondary) granules (SG), and gelatinase (tertiary) granules (GG). These structures fill the neutrophil cytoplasm, and each granule type contains molecules that contribute to host defense (Borregaard *et al.*, 2007; Pham, 2006), as shown in Figure 4. Conversely, the abundance of 'typical' organelles including mitochondria, endoplasmic reticulum, Golgi, early endosomes, and late endosomes is significantly diminished.

Speed and efficiency are defining features of phagosome maturation in neutrophils, and all three granule types are mobilized within seconds of microbe or particle binding (Figure 4). Thus, phagosome-granule fusion can be detected even before phagosome sealing and this process goes to completion within minutes (Tapper *et al.*, 2002; Bainton, 1973). Near-simultaneous delivery of SG and AG components to phagosomes is critical for cooperation among host defense mechanisms and is essential for optimal microbe killing. For example, the AG enzyme proteinase 3 processes the SG protein hCAP-18 to its active form, which is called LL-37 and kills bacteria via membrane disruption (Pham, 2006). As noted above, the catalytic core of the NADPH oxidase complex, flavocytochrome b₅₅₈, is stored in SG and to a lesser extent in GG, whereas MPO is stored in AG, and MPO allows neutrophils to convert NADPH oxidase-derived ROS into highly toxic HOCl in the phagosome lumen (Figure 2). The roles of other granule components in host defense are discussed below.

The mechanisms that regulate phagosome maturation in neutrophils are not well defined at the molecular level. It has been known for some time that degranulation is influenced by intracellular calcium, with progressively higher concentrations of this cation required for mobilization of GG, SG, and AG (Tapper *et al.*, 2002). Nonetheless, recent studies of Tapper and colleagues demonstrate that the role of calcium in phagosome-AG fusion is more complex than previously appreciated, as AG fusion with forming phagocytic cups is calcium-dependent whereas AG fusion with sealed phagosomes is not (Nordenfelt and Tapper, 2010, 2011; Nordenfelt *et al.*, 2009). Other molecules that have been implicated in AG mobilization include Rab27a, Munc13-4, Munc18-2, Rac, and the tyrosine kinase Hck (Monfregola *et al.*, 2012; Catz, 2013; Brochetta *et al.*, 2008; Abdel-Latif *et al.*, 2005; Welch *et al.*, 1996; N'Diaye *et al.*, 1998). In contrast, another Munc18 isoform, Munc18-3, preferentially associates with SG and GG (Brochetta *et al.*, 2008), and the efficiency of SG-phagosome fusion is influenced to some extent by opsonins and the receptors used for particle uptake (Joiner *et al.*, 1989).

It is also important to note that some proteins that localize to late endosomes and lysosomes in macrophages have a different subcellular localization in neutrophils. For example, CD63, lamp-1, and lamp-2 are all markers of macrophage late endosomes, yet in neutrophils CD63 is an AG marker, but lamp-1 and lamp-2 are not (Dahlgren *et al.*, 1995; Kallquist *et al.*, 2008). Rather, lamp-1 and lamp-2 associate with residual late endosome-like organelles in neutrophils along with Rab7, and Rab5 associates with neutrophil early endosomes. Rab5, Rab7, and lamp-1 have been detected on neutrophil phagosomes in some studies but not in others (Perskvist *et al.*, 2001; Minakanmi *et al.*, 2010; Nordenfelt and Tapper, 2011). The contribution of neutrophil endosomes to microbe killing remains uncertain because of their low abundance, and

because host defense molecules associated with endosomes in other cell types, such as lysozyme, cathepsins, and V-ATPase, localize instead to neutrophil AG. Indeed, AG and to a lesser extent SG are considered to be the lysosome-like compartments of neutrophils.

Oxygen-Independent Killing

Mechanisms for microbe killing that do not require oxygen are essential for host defense, as oxygen concentrations in many tissues and in abscesses are very low. Synergy between multiple defense mechanisms increases the efficacy of microbe killing, and in as much as certain microorganisms are preferentially controlled by ROS, others are predominantly controlled by nonoxidative mechanisms. Processes and molecules that comprise the oxygen-independent killing arsenal of phagocytes include phagosome acidification, iron sequestration, cationic antimicrobial peptides, and degradative enzymes. Some of these mechanisms are common to both macrophages and neutrophils, whereas others are cell type-specific.

V-ATPase and phagosome acidification

As noted above, macrophage phagosomes become progressively more acidic as they mature in parallel with accumulation of V-ATPase in the phagosome membrane. The pH of mature phagolysosomes can be as low as 4.5, and very few microbes are able to survive under these conditions. In addition to the direct toxicity of acidic pH, phagosome acidification is also required for phagosome-lysosome fusion in macrophages, and this process is blocked by V-ATPase inhibitors as well as agents that artificially elevate compartment pH, such as NH_4Cl (Hart and Young, 1991; Farin and Grinstein, 2012). Neutrophil phagosomes acquire V-ATPase from AG (Feuk-Lagerstedt *et al.*, 2007). Nonetheless, phagosomes in this cell type remain near neutral pH during the first hour after particle uptake, in parallel with robust NADPH oxidase activation (Nordenfelt and Tapper, 2011).

Lactoferrin, transferrin, and iron sequestration

Iron is an essential micronutrient that is required by microbes as well as host cells for their growth and survival. Limiting the availability of free iron for capture and use by microbes is therefore an important aspect of host defense and illustrates the concept of 'nutritional immunity' (Jurado, 1997). Iron sequestration is mediated primarily by transferrin and lactoferrin, which are delivered to macrophage and neutrophil phagosomes from early endosomes and SG, respectively (Figures 3 and 4; Pham, 2006; Borregaard *et al.*, 2007; Vieira *et al.*, 2002). Of note, lactoferrin is also secreted by epithelial cells and is present at high concentrations in tears, breast milk, respiratory and cervical secretions, seminal plasma and other extracellular fluids, and in this manner contributes to elimination of bacteria, viruses, and fungi in the extracellular space (Legrand *et al.*, 2005).

Defensins, LL-37, and other antimicrobial peptides

Antimicrobial proteins and peptides (AMPs) are ancient components of host defense that contribute to intraphagosomal killing by neutrophils and are also secreted into

extracellular fluids by epithelial cells at mucosal surfaces and in the skin (Wiesner and Vilcinskas, 2010). Neutrophil AMPs include the cathelicidin LL-37, the α -defensins HNP-1-HNP-4, and bacteriocidal permeability-increasing protein (BPI) (Borregaard *et al.*, 2007; Wiesner and Vilcinskas, 2010). All AMPs are cationic, and for this reason bind avidly to the negatively charged surfaces of microbes. Cathelicidins are peptides that disrupt microbe membranes. The α -defensins have similar effects on microbe membranes and may also inhibit DNA, RNA, and protein synthesis. Similar to α -defensins, BPI is stored in AGs and is delivered into neutrophil phagosomes. However, BPI is unique among AMPs as a full-length protein with two functional domains that facilitates elimination of gram-negative bacteria by multiple mechanisms (Schultz and Weiss, 2007). Specifically, the N-terminal domain of BPI binds LPS and neutralizes its proinflammatory capacity, and the C-terminal domain facilitates bacterial clearance. Additional AMPs, including those of the human β -defensin family, are synthesized and secreted by epithelial cells (Wiesner and Vilcinskas, 2010).

Degradative enzymes

Many enzymes contribute to microbe killing and degradation in phagosomes (Pham, 2006; Thorne *et al.*, 1976). Among these, elastase degrades proteins in the outer membranes of gram-negative bacteria, leading to membrane fragmentation and bacterial death, whereas enzymes of the cathepsin family can induce death of gram-positive bacteria. Lysozyme specifically degrades peptidoglycan, which is a structural component of the cell walls of both gram-positive and gram-negative bacteria. Cooperation between enzymes also increases killing efficiency. For example, elastase and cathepsins collaborate for intraphagosomal killing of fungi, whereas elastase-mediated degradation of the outer membranes of gram-negative bacteria increases lysozyme access to peptidoglycan in the intermembrane space. Finally, arginase is present in human neutrophils and murine macrophages, and catalyzes the conversion of arginine into urea and citrulline. As urea is a substrate for iNOS, arginase contributes indirectly to oxygen-dependent microbe killing.

Autophagy and Xenophagy

Autophagy (self-eating) is a conserved catabolic process that was first described as a mechanism to delay or prevent cell death in response to nutrient starvation (Levine *et al.*, 2011; Green and Levine, 2014). During starvation-induced autophagy crescents of membrane call phagophores (or isolation membranes) appear in the cytoplasm. These structures expand and then close to form double-membrane vesicles called autophagosomes. Under these conditions the content of each autophagosome is a random sample of cytoplasmic organelles and proteins that are subsequently delivered to lysosomes for degradation and amino acid reutilization. It was subsequently discovered that autophagy is also essential for degradation of damaged or aged mitochondria, peroxisomes, other organelles, as well as protein aggregates that are too large to fit inside the proteasome. In this case, selectivity is achieved by the use of cargo capture receptors (p62, NBD52, and NBR1). In brief, the organelles or proteins to be degraded are tagged with

ubiquitin, which allows them to bind one or more cargo capture receptors. These receptors can also bind LC3-II, a protein that is found exclusively in the phagophore membrane, thereby ensuring that the cargo of interest will be tethered to and trapped inside the forming autophagosome. The importance of selective autophagy to normal cell function is illustrated by the fact that defects in this process contribute to aging and to the pathology of many diseases, including Parkinson's disease, Huntington's disease, and Alzheimer's disease. Selective autophagy is also required for elimination of mitochondria and other organelles during red blood cell development.

Xenophagy

Xenophagy (foreign-eating) is essential for innate defense and refers to the use of selective autophagy by macrophages as a method to capture bacteria, fungi, parasites, and viruses inside autophagosomes, with subsequent fusion with lysosomes for elimination (Levine *et al.*, 2011; Figure 5). In practical terms, xenophagy gives macrophages a second chance to kill pathogens that inhibit or evade conventional phagosome maturation. For example, *Mycobacterium tuberculosis* inhibits phagosome maturation and replicates in compartments that resemble early endosomes, whereas *Listeria monocytogenes* escapes the phagosome and replicates in macrophage cytosol. Nonetheless, following induction of xenophagy, cytosolic *Listeria*, and intraphagosomal *Mycobacteria* can both be sequestered inside autophagosomes (Figure 5), and once formed these compartments mature by sequential interactions with late endosomes and lysosomes in a manner similar to the typical phagosome maturation pathway discussed above.

Cell Death Mechanisms and Host Defense

Several mechanisms of regulated (programmed) cell death have been described. Among these, pyroptosis and apoptosis

Figure 5 Xenophagy. The ability of autophagosomes to capture microbial pathogens and deliver them to lysosomes for degradation and killing is called xenophagy. Autophagosomes (AP) are double-membrane structures that can either capture bacteria replicating in macrophage cytosol, such as *L. monocytogenes*, or can ensnare whole phagosomes containing pathogens such as *M. tuberculosis* (Mtb), that otherwise blocks phagosome maturation and phagosome-lysosome fusion.

are critical for microbe killing and regulation of the inflammatory response by phagocytes. Another process, neutrophil extracellular trap formation, impairs bacterial spreading throughout an infected host and can also be coupled to cell death.

Pyroptosis

Pyroptosis is a proinflammatory form of macrophage death that is evoked by detection of pathogen components in the cytosol. 'Contamination' of the cytosol can occur by multiple mechanisms. As noted above, some pathogens escape from the phagosome to the cytosol, and bacterial replication releases small amounts of DNA, peptidoglycan, and proteins in this locale. Other pathogens act from the cell surface or from inside phagosomes by releasing toxins or using type III or type IV secretion systems to inject bacterial 'effector proteins' directly into the cytosol in order to manipulate the cytoskeleton, membrane trafficking, or other aspects of cell function as part of their virulence strategies. Proteins of the NOD-like receptor (NLR) family allow detection of microbe components in the cytosol (Broz and Monack, 2011; Elinav *et al.*, 2011). For example, AIM2 detects cytosolic DNA, NLRC4 detects secreted effector proteins, and NLRP1 detects secreted toxins. The NLRs then initiate formation of an inflammasome complex for activation of an enzyme called caspase-1. Active caspase-1 catalyzes the activation and secretion of two proinflammatory cytokines, IL-1 β and IL-18, and also induces plasma membrane disruption and cell death (Broz and Monack, 2011; Elinav *et al.*, 2011; Figure 6). This mechanism of cell death is proinflammatory because it is coupled to cytokine secretion, and because macrophage lysis also allows other proinflammatory molecules to be released into the extracellular space, including DAMPs. Inflammasome activation and

Figure 6 Macrophage pyroptosis. Pyroptosis is a proinflammatory form of cell death. Central to this process is caspase-1, which activates proinflammatory cytokines such as IL-1 β and IL-18. Other features of pyroptosis are DNA damage and loss of plasma membrane integrity. In particular, ion flux across the cell membrane and osmotic swelling leads to cell lysis and death. Concomitant spilling of cytotoxic cell contents, including DAMPs, is also proinflammatory. Pyroptosis contributes to host defense by inducing inflammation and by depriving intra-macrophage pathogens of their replicative niche. DAMPs, damage-associated molecular pattern molecules.

pyroptosis contribute to host defense by depriving intra-macrophage pathogens (such as *Listeria* and *Salmonella*) of their replicative niche. In addition, IL-1 β recruits neutrophils, which engulf and kill the released organisms (Elinav *et al.*, 2011). Thus, the contribution of pyroptosis to host defense requires cooperation between phagocyte types, and also illustrates the fact that most intra-macrophage pathogens are readily eliminated by neutrophils.

Apoptosis

Unlike macrophages which can survive for months, neutrophils are very short lived and are preprogrammed to die by constitutive apoptosis approximately 24 h after release into the bloodstream. For this reason, humans produce 10^{11} new neutrophils each day. Elegant studies of DeLeo and colleagues demonstrated that apoptosis is a final, regulated stage of the neutrophil lifecycle that is driven not only by intracellular signaling, but also by changes in gene expression that collectively comprise an 'apoptosis differentiation program' (Kobayashi *et al.*, 2003). Typically, neutrophil apoptosis is accelerated further by phagocytosis that is coupled to NADPH oxidase activation, and this phagocytosis-induced cell death response also requires changes in gene expression (Kobayashi *et al.*, 2002). During this process, neutrophil functional and proinflammatory capacity are downregulated, and the dying cells express surface markers that facilitate their internalization by macrophages via a process called efferocytosis. Rapid and efficient clearance of dying neutrophils by this mechanism is noninflammatory, and is therefore essential for daily neutrophil turnover and for restoration of tissue homeostasis following infection. Consistent with this, defects in neutrophil turnover and efferocytosis are indicative of a defective and aberrantly regulated inflammatory response that favors neutrophil progression to necrosis, exacerbates tissue destruction, and impairs microbe clearance. Inflammatory diseases associated with abnormal apoptosis include chronic obstructive pulmonary disease and rheumatoid arthritis (McCracken and Allen, 2014). In addition, bacterial pathogens that evade

elimination by neutrophils can affect the viability of these cells in two different ways. Pathogens that can grow inside neutrophils, such as *Anaplasma phagocytophilum* and *Francisella tularensis*, inhibit apoptosis and prolong the lifespan of the host cell to sustain the viability of their replicative niche, whereas extracellular bacteria, such as *Streptococcus pyogenes*, secrete toxins that induce neutrophil lysis in order to curtail intracellular killing and regain access to the extracellular milieu (McCracken and Allen, 2014).

Neutrophil Extracellular Traps and NETosis

Neutrophil extracellular traps (NETs) are complexes of chromosomal DNA, histones, and granule proteins that are released by neutrophils and ensnare extracellular microbes (Yipp and Kubes, 2013; Figure 7). As originally described, NET deployment is coupled to plasma membrane disruption and therefore culminates in a form of cell death called 'NETosis.' An initiating event in this process is robust NADPH oxidase activation at the plasma membrane, as occurs on response to soluble stimuli such as phorbol esters. Subsequent ROS-induced DNA damage leads to chromatin decondensation and loss of nuclear membrane integrity. Chromatin then mixes with elastase and other enzymes released into the cytosol from oxidant-damaged granules prior to cell lysis, DNA release, and NET formation (Figure 7). Additional *in vivo* and *in vitro* studies indicate that NET formation can also occur by mechanisms that do not require ROS, and by mechanisms that involve incremental DNA release and preserve cell viability and functional capacity (Yipp and Kubes, 2013). Thus, although our understanding of mechanisms that lead to NET formation is incomplete, it is established that trapping of extracellular bacteria and fungi in these structures can curtail their dissemination and limit the spread of infection, even if the NETs are not necessarily microbicidal.

Pathogen Subversion of Host Defense

Much of what is known about phagocyte function and mechanisms of host defense has been informed by studies of

Figure 7 NETs and NETosis. Under certain circumstances ROS generated by activated neutrophils can disrupt both granule and nuclear membrane integrity. This allows granule proteins such as elastase and MPO to enter the nucleus and bind chromatin. Subsequent rupture of the plasma membrane allows deployment of this complex of DNA and granule proteins as a 'NET' or neutrophil extracellular trap that can ensnare extracellular bacteria and prevent their dissemination. Neutrophil death that is coupled to NET release is called NETosis.

microbial pathogens that perturb macrophage and neutrophil function as part of their virulence strategies (Smith and May, 2013; McCracken and Allen, 2014; Reddick and Alto, 2014). Although a detailed discussion of this topic is beyond the scope of this article, mechanisms of evasion include avoidance or inhibition of phagocytosis, disruption of NADPH oxidase assembly, activation or targeting, blockade of phagosome maturation at various stages of the pathway in either macrophages or neutrophils, neutralization of phagosome pH or adaptation for survival in acidic lysosomes, neutralization of AMPs, secretion of siderophores for iron capture that counteract the withholding effects of lactoferrin and transferrin, disruption of phagosome integrity and escape to the cytosol, interference with microbe detection systems including NLRs, and manipulation of phagocyte viability of mechanisms of cell death including apoptosis and pyroptosis.

Summary

Both macrophages and neutrophils are essential for microbe killing and host defense. These white blood cells accumulate at sites of infection and in this locale engulf bacteria and other microbes using a receptor and actin-dependent process called phagocytosis. The NADPH oxidase complex, AMPs, degradative enzymes, and iron sequestering proteins constitute the killing arsenal of macrophages and neutrophils, and allow creation of a highly lethal intraphagosomal environment. Concentration of these defense systems in close proximity to the ingested prey and collaboration between the different enzymes and molecules increases intracellular killing capacity and the efficiency of this process. Regulated mechanisms of cell death, including apoptosis and pyroptosis, also contribute to antimicrobial defense and regulation of the inflammatory response, and much of what we have learned about these processes has been informed by studies of bacterial and fungal pathogens that subvert certain aspects of macrophage or neutrophil defense in order to cause disease.

Bacterial Subversion of Phagocytic Killing

RR Isberg, S Asrat, DA de Jesús, AD Hempstead, and V Ramabhadran, Tufts University School of Medicine, Boston, MA, USA

Introduction

The default pathway for uptake of bacteria by mammalian cells leads to the formation of a membrane-bound phagosome that matures and eventually fuses with lysosomal compartments. Movement via this pathway is usually thought to be antimicrobial because it immediately activates oxygen-dependent killing by the NADPH oxidase complex. Whether a microbe will survive this attack, is a further danger from acidic organelles such as lysosomes, which are sites of concentrated antimicrobial molecules including proteases and small antimicrobial peptides (Asrat *et al.*, 2014). As uptake by macrophages and neutrophils is a primary host innate defense against disease, many pathogenic bacteria have strategies to either prevent phagocytosis, or change the progression of the uptake pathway so that antimicrobial activities can be suppressed and microbial survival and growth can be supported. As a rule, extracellular pathogens attempt to prevent phagocytosis, while intracellular pathogens allow uptake, but support intracellular routing in a fashion that avoids degradation and attack by the host cell. In this article, we will review these strategies.

Interference of Uptake by Bacterial Pathogens

After microbial entry into the host, the first interaction is with either the mucosal layer or the host cell plasma membrane. In case of an encounter with phagocytic cells, contact with the plasma membrane can lead to uptake and phagocytic killing. An efficient mechanism to avoid targeting by phagocytic cells is to directly misregulate or destroy target cells via a focused pathogen attack on the plasma membrane.

Blocking Uptake via the Deposition of Bacterial Pore-Forming Toxins

A common strategy of targeting phagocytes is for extracellular pathogens to synthesize soluble oligomeric proteins that, on contact with host cells, form pores (Gonzalez *et al.*, 2008). The pore-forming toxins (PFTs) can have either α -helical or β -sheet structures that form a channel in the target plasma membrane. Cholesterol-dependent cytolysins are the best characterized of the β -sheet class, forming oligomers of approximately 35–44 monomers after targeting host cell cholesterol via a Thr-Leu motif on the toxins (Dunstone and Tweten, 2012). The toxins that form α -helical motifs in the target plasma membrane are made of monomers with a central hydrophobic helix that generates a pore via oligomerization after partial unfolding (Gonzalez *et al.*, 2008).

PFTs play a number of roles in the disease process, including killing phagocytes and targeting lymphocytes for destruction, and it is common for a single bacterial pathogen to encode multiple types of toxins. The membrane receptors

targeted by these toxins can also be diverse, which allows the targeting of specific cell types. For instance, *Staphylococcus aureus* has multiple PFTs with distinct cell tropisms based on their receptor binding profiles (Dumont and Torres, 2014). Receptors include ADAM10, which is located on a number of host cell types, and is targeted by Staphylococcal α -hemolysin, resulting in either lysis or altered regulation of host cell signaling pathways, such as enhanced chemokine secretion in neutrophils and cellular proliferation of keratinocytes. Another receptor targeted is the HIV co-receptor CCR5 by the LukED toxin. Binding via this receptor allows killing of macrophages and dendritic cells, while binding of the non-cholesterol-dependent LukED to CXCR1 and CXCR2 is linked to killing of neutrophils (Reyes-Robles *et al.*, 2013).

Inactivation of Phagocytosis After Intimate Contact with Pathogens

After contact with phagocytes, a number of pathogens are able to misregulate phagocytic signaling, interfering with uptake and locking the pathogen on the host cell surface. The most common strategy for accomplishing this task involves translocating bacterial-encoded misregulators into host cells using type III secretion systems (T3SS) (Burkinshaw and Strynadka, 2014). T3SS are multiprotein complexes that form needle-like structures, assembled in the envelope of many gram-negative bacterial pathogens. They are thought to inject proteins directly through the host cell plasma membrane. The best characterized of these translocated antiphagocytic proteins are Rho GTPase-activating proteins (RhoGAPs). These proteins target multiple Rho family members, known to be central regulators of actin polymerization events that support phagocytic cup formation. The RhoGAPs act by stimulating the rate of intrinsic GTPase hydrolysis, resulting in a Rho family protein that is charged with GDP and therefore inactive.

Each member of the *Yersinia* species, including the causative agent of bubonic plague *Yersinia pestis*, encodes a T3SS that translocates YopE, a RhoGAP that targets RhoA, RhoG, Rac1, and Cdc42, inhibiting phagocytosis (Black and Bliska, 2000). Similarly, the *Pseudomonas aeruginosa* ExoS protein has RhoGAP activity that interferes with phagocytosis (Goehring *et al.*, 1999). A different strategy of targeting Rho family members is taken by the extracellular *Vibrio parahaemolyticus* species. The *V. parahaemolyticus* T3SS substrate VopS AMPylates Rho, Rac, and Cdc42, resulting in steric hindrance that prevents interactions of Rho family members with downstream effectors of actin-mediated rearrangements (Yarbrough *et al.*, 2009).

After contact with pathogens, phagocytes can target the microbe for destruction via both oxygen-dependent and -independent pathways. The most important pathway for O₂-dependent killing is via the assembly and activation of the NADPH oxidase complex on the plasma membrane.

Pathogens can overcome this form of killing by either directly inactivating components of the complex, or by inducing a form of uptake into host cells that avoids activation of the complex. For the most part, the mechanistic bases of these strategies are poorly understood, although it is clear that the bacterial proteins that interfere with phagocytosis also directly target the NADPH oxidase complex. For instance, assembly of this complex requires Rac2 and/or Rac1, depending on the cell-type, to promote assembly (Hordijk, 2006). The *Yersinia* YopE RhoGAP protein inactivates both of these Rho family members and prevents the oxidative burst. Therefore, a single bacterial protein can interfere with two distinct steps in phagocytic killing, by preventing O₂-dependent killing and uptake into a compartment that could target the bacterium to be killed by O₂-independent strategies.

The Replication Vacuole 1: Manipulation of the Endocytic Pathway to Support Bacterial Replication

Phagosome acidification and targeting into a degradative lysosome is an O₂-independent strategy that leads to microbial demise, and arrest or bypass of this trafficking pathway is a common strategy used by bacterial pathogens that grow in membrane-bound vacuoles. Pathogens such as *Mycobacterium tuberculosis* (*Mtb*), *Legionella pneumophila*, *Salmonella enterica* serovar Typhimurium and *Chlamydia trachomatis* appear to interfere with acidification and, depending on the pathogen, can be internalized via a pathway that totally bypasses entry into endocytic compartments. In some cases, maturation and acidification of the vacuole seem to be encouraged, as exemplified by *Brucella abortus* and *Coxiella burnetii*. These pathogens use strategies to convert normally antimicrobial environments of phagolysosomes into ones that support microbial replication.

Blockade of Endocytic Maturation

Tuberculosis is caused by the growth of *M. tuberculosis* within lung alveolar macrophages. After uptake, the compartment harboring *Mtb* appears to mimic early endosomes, but there is a block in acidification and little evidence for further progress down the endocytic path. This block requires the bacterial ESX-1 secretion system (MacGurn and Cox, 2007). As expected for a compartment with impaired acidification, there is reduced acquisition of the v-ATPase, which may be due to a blockade in maturation from a Rab5-rich to a Rab7-rich compartment (Via et al., 1997; Gonzalez et al., 2008). *Mtb* also releases a number of bioactive lipids as well as manipulates host lipid signaling pathways to prevent maturation of the bacterium-containing compartment. The bacterial lipids include manose-capped lipoarabinomannan (ManLAM), which lowers phosphatidylinositol-3-phosphate (PI3P) levels on the vacuolar membrane, possibly by interfering with Ca²⁺ flux (Vergne et al., 2005). Similarly, the bacterial SapM phosphatase targets PI3P to generate PI, which further blocks maturation into a late phagosome (Vergne et al., 2005). Another strategy for interfering with maturation involves the secreted phosphatase PtpA, which targets the vacuolar protein VPS33B, a regulator of

fusion of compartments within the lysosomal network (Bach et al., 2008).

Survival After Entry into the Endocytic Pathway

An excellent example of a bacterial species that survives after entering into an endocytic pathway is *Salmonella*. Immediately after pathogen-induced uptake by T3SS-translocated proteins, the bacterium is found in a compartment that has some characteristics of both early and late endosomes. Host proteins Rab5 and the PI3-kinase hVPS34, diagnostic of an endocytic route, are observed on the *Salmonella*-containing vacuole (SCV), with consequent PI3P accumulation (Bakowski et al., 2010). Accumulation of this lipid species prevents docking of the recycling Rab35 GTPase (Heo et al., 2006).

Once SCV construction is initiated, there is a selective series of interactions that appear to mimic movement into a lysosomal niche, but clearly keep the microbe separate from antimicrobial effectors of the host. Although markers such as EEA1, Rab5, Rab7, and Lamp-1/2, indicative of some maturation along the endocytic pathway are localized to the SCV, clear steps are taken to prevent entry into a lysosomal compartment (Figure 1; Méresse et al., 1999). There is an absence of key markers of the endocytic path on the SCV, such as mannose-6-phosphate receptors, but there may be some limited exchange of material with lysosomes, making the SCV into a compartment of unique composition (Drecktrah et al., 2007).

Pathogens That Intimately Interact with Lysosomal Components

The gram-negative pathogens *Coxiella burnetii* and *B. abortus* appear to actively enter into a compartment that is lysosomal in nature. The Q-fever agent, *C. burnetii* constructs a vacuole that, similar to *Salmonella*, accumulates Rab5 followed by Rab7 (Romano et al., 2007). Initially, the *Coxiella*-containing vacuole (CCV) forms a compartment with the membrane in tight opposition to the bacterium. This tight vacuole enlarges as a result of fusion to both endocytic compartments as well as to other CCVs (Coleman et al., 2004; Figure 1). Eventually, the CCV occupies most of the host cell cytoplasm (Coleman et al., 2004). Unlike the SCV, the CCV has clear phagolysosomal characteristics, with presence of markers of the lysosome, such as cathepsin D (Romano et al., 2007).

Formation of the CCV requires that the bacterium assemble a dedicated protein translocation system called a type IV secretion system (T4SS). In addition, the function of specific v-SNAREs, such as VAMP7 and VAMP3, is required for full maturation into large CCVs (Campoy et al., 2013). One T4SS translocated substrate known to be critical for successful CCV formation is CvpA, which interacts with the clathrin complex adaptor protein AP2 (Larson et al., 2013). In addition, CCV formation probably involves interaction with the *trans*-Golgi network (TGN), as the retromer complex is necessary for maturation of the vacuole (McDonough et al., 2013).

In the case of *B. abortus*, construction of the *Brucella*-containing vacuole (BCV) involves early contact with lysosomal compartments (Atluri et al., 2011). Fusion with the lysosome

Figure 1 Targeting of host organelles by bacterial pathogens. Shown are a variety of bacterial pathogens that grow within vacuolar compartments. *Salmonella* and *Coxiella* are found in compartments that have proteins associated with the endocytic pathway, whereas other intracellular pathogens avoid this route. In the case of *Coxiella*, the bacterium-containing compartment moves deep into the endocytic pathway, fusing with the lysosome, while with *Salmonella*, movement is truncated. *Legionella* and *Chlamydia* avoid entry into this route. *Legionella* interacts intimately with ER-derived membrane components while the chlamydial inclusion recruits ceramide transfer protein (CERT) and associates with the ER and the Golgi. Reproduced from Asrat, S., De Jesus, D.A., Hempstead, A.D., Ramabhadran, V., Isberg, R.R., 2014. Bacterial pathogen manipulation of host membrane trafficking. *Annual Reviews of Cell and Developmental Biology* 30, 79–109.

appears transient, but is necessary for vacuole construction and initiating intracellular growth. Interestingly, this early event, which is associated with acidification, may activate the bacterial T4SS (Boschiroli *et al.*, 2002). After initial lysosomal interactions, T4SS translocated substrates block further maturation, and prevent the appearance of lysosomal markers such as cathepsin D (Atluri *et al.*, 2011). Once this transient interaction with the lysosome is complete, endoplasmic reticulum (ER)-derived vesicles are recruited to the BCV to mature it into a replication-competent vacuole. Bacterial components other than the T4SS, and its effectors, are also important for BCV construction. For example, the bacterial cyclic β -1,2 glucan interferes with long term BCV-lysosome

fusion, presumably by disrupting lipid rafts (Arellano-Reynoso *et al.*, 2005).

The Replication Vacuole 2: Manipulation of the Secretory Pathway to Support Bacterial Replication

A common strategy to avoid internalization into an endocytic antimicrobial pathway is for the pathogen to induce uptake in a fashion that promotes immediate interaction with the secretory pathway. This allows the bacterium to totally bypass many of the default killing mechanisms associated with phagocytosis. Numerous pathogens use this strategy by translocating

microbial molecules into the host cell that control the nature of the trafficking of the bacterium-containing compartment.

Intimate Interaction with the Reticulum

Targeting of ER dynamics as a strategy to allow pathogen replication is best characterized with the causative agent of Legionnaire's disease, *L. pneumophila*. A pathogen of amoebae in the environment, the organism grows within alveolar macrophages during human disease in the *Legionella*-containing vacuole (LCV) that is closely associated with rough endoplasmic reticulum (RER) (Isberg *et al.*, 2009). Interactions with the host cell early secretory pathway, involving budding of vesicles from the ER, occurs almost immediately after contact with host cells as a consequence of bacterial proteins translocated into the host cell via a T4SS.

Consistent with the microbe targeting membrane traffic that exits the ER, *L. pneumophila* translocates a large number of proteins that control steps associated with this process. The Rab1 GTPase, which modulates docking and fusion of ER-derived vesicles with downstream compartments such as the Golgi, is a common target of many of these bacterial proteins. The incredible diversity of strategies used to control this GTPase indicates that the bacterium takes over total control of its function throughout the replication cycle. Rab1 is recruited and activated by the SidM/DrrA guanine nucleotide exchange factor (GEF), and the Rab1GAP LepB can reverse its activation (Ham and Orth, 2011). Additionally, the Rab1 GTPase can be locked in its nucleotide-bound form in a number of ways. SidM/DrrA has a domain that activates Rab1 by adenylation (AMPylation), while SidD can reverse this activation by removing the modification. Finally, both LidA and AnkX can lock Rab1 in the nucleotide-bound form that the GTPase assumes at the time of contact (Tan and Luo, 2011). AnkX performs this function by a novel phosphorylcholine reaction, which can be reversed by the *L. pneumophila* Lem3 protein (Tan *et al.*, 2011).

Added onto this hijacking of Rab1 function are multiple other levels of attack on the host cell early secretory apparatus. The bacterial RalF protein was the first *Legionella* T4SS translocated substrate identified, and is responsible for activation of Arf1, a GTPase involved in vesicle egress from the ER (Isberg *et al.*, 2009). SNARE proteins are also targeted. Activation of Rab1 by SidM/DrrA promotes the formation of an unusual pairing of ER-derived and plasma membrane (PM)-derived SNARE proteins, potentially driving a membrane docking and fusion event between these two membrane sites. This event involves forming a Stx3/Stx4 (PM) and Sec22b (ER) complex, a process that requires active Sar1 and Arf1 (Figure 1; Arasaki *et al.*, 2012). Finally, *Legionella* inhibits retrograde traffic from the Golgi. The bacterial T4SS substrate RidL binds to the retromer protein VPS29, preventing accumulation of cargo receptors on the LCV (Finsel *et al.*, 2013).

In contrast to *Legionella*, *Brucella* hijacks retrograde Golgi-ER traffic. Although budding from the ER is necessary for construction of the *Brucella*-containing vacuole (BCV), the Rab1 GTPase that is involved in anterograde traffic is dispensable (Atluri *et al.*, 2011). Consistent with the model that retrograde transport is important for BCV formation, the retrograde GTPase Rab2 is critical for bacterial replication

(Fugier *et al.*, 2009). In fact, *Brucella melitensis* encodes a protein, RicA, which binds to the GDP-bound form Rab2, but there is no evidence that this protein modulates GTPase activity (de Barsy *et al.*, 2011). The details of establishment of the BCV are still being worked out, but similar to *Legionella*, the control of replication vacuole formation by T4SS translocated proteins appears to hold true. For instance, the T4SS substrate SepA was shown to be important during early stages of BCV establishment, and in its absence there is increased fusion of the BCV with lysosomes (Dohmer *et al.*, 2014).

In addition to pathogens that hijack retrograde or anterograde secretory traffic in host cells, some take advantage of bidirectional traffic to control formation of the vacuole that harbors the pathogen. In the case of *Salmonella* species, this results in the SCV assuming a tubular structure in epithelial cells (called a Sif) although the SCV in macrophages does not appear filamentous. Formation of the SCV involves positive interactions with retromer cargo proteins and sorting-nexin proteins-1 and 3 (SNX1 and SNX3) (Bujny *et al.*, 2008). In addition, the SCV must associate with the Golgi. This is apparently mediated by transient interactions with Rab7 and its effector RILP which allows positioning of the SCV in a perinuclear site (Guignot *et al.*, 2004).

Formation of Sifs appears to be tightly linked to the control of kinesin. To this end, a number of *Salmonella* T3SS substrates modulate kinesin function. For instance, kinesin-1 is recruited by the bacterial PipB2 protein (Henry *et al.*, 2006; Figure 1). By far, the most important bacterial protein for controlling this structure is the SifA protein, which controls Sif formation by modulating activities of a number of proteins associated with microtubule and membrane trafficking dynamics. Early in infection, RILP is recruited to the vacuole, and this is potentially terminated by SifA-Rab7 interactions (Harrison *et al.*, 2004). Secondly, SifA controls kinesin function by binding to the host protein kinesin-1-interacting protein SKIP, which promotes Sif formation by stimulating anterograde transport of vesicles from the replication compartment (Boucrot *et al.*, 2005). In the absence of SifA or SKIP, a proper replication compartment cannot form, and intracellular replication is defective (Boucrot *et al.*, 2005).

SifA may play a role in coordinating control of the microtubule network with Rab-regulated membrane dynamics, although there are some differences regarding mechanistic details of these interactions. It was first shown that SifA acts to interfere with the function of the late endosomal GTPase Rab9 by outcompeting its binding to SKIP, which is thought to control the distribution of LAMP1-containing compartments (Jackson *et al.*, 2008). Recent data suggests that dual control of Rab9 and SKIP enables *Salmonella* to manipulate mannose phosphate receptor (MPR) traffic and lysosomal degradation (McGourty *et al.*, 2012). By looking at either model, it is reasonable to speculate that the inability of SifA to control Rab9 function results in a defective niche that cannot protect the bacterium.

Salmonella is not the only pathogen that translocates proteins to support maintenance of replication vacuole integrity. The *Legionella* T4SS SdhA protein prevents the vacuole from falling apart, ensuring that microbial products do not contaminate the host cell cytosol and induce inflammatory signaling (Creasey and Isberg, 2014). There are a number of

functional similarities between SifA and SdhA, even though the proteins show no sequence similarity. For instance, *sdhA* and *sifA* mutations both cause replication vacuole rupture. Secondly, in each case, the instability of the compartment can be partially reversed by deleting a bacterial phospholipase gene (Creasey and Isberg, 2014; Ruiz-Albert *et al.*, 2002). Finally, both appear to control microtubule function.

The Replication Vacuole 3: Multi-Organelle Interactions

Chlamydia trachomatis is an obligate gram-negative bacterium that undergoes a developmental switch to promote disease in its hosts. The elementary body (EB) developmental form is infectious and is internalized into cells, where it differentiates into the reticulate body, which is the replicative form. After internalization, and simultaneously with this developmental switch, the compartment holding the bacterium forms a replication vacuole, called an inclusion, whose formation is promoted by a number of bacterial proteins called Incs that insert into the vacuole membrane (Mital *et al.*, 2010). The inclusion localizes to a perinuclear locale where it avoids fusion with lysosomal compartments. This locale in the cell appears perfectly situated to interface with anterograde traffic from the Golgi, and the bacterium directly manipulates Golgi structure and traffic. The bacterium promotes cleavage of Golgin-84, which results in formation of Golgi mini-stacks in cells harboring *C. trachomatis* (Heuer *et al.*, 2009). This fragmentation appears to allow movement of ceramide into the inclusion, which is then incorporated as sphingomyelin into the inclusion membrane (Heuer *et al.*, 2009). The importance of sphingolipid incorporation is emphasized by the fact that interference of trafficking of ceramide impairs *Chlamydia* development and causes loss of inclusion membrane integrity (Heuer *et al.*, 2009; Elwell *et al.*, 2011; Derre *et al.*, 2011).

Sphingomyelin biosynthesis on the inclusion membrane appears to be a consequence of nonvesicular trafficking of ceramide, and this is the first evidence that nonvesicular traffic contributes to intracellular survival of pathogens (Elwell *et al.*, 2011; Derre *et al.*, 2011). There is clear docking between the ER-localized ceramide transfer protein CERT and the inclusion that is mediated by the bacterial IncD protein, indicating that the bacterial replication compartment controls both ER and Golgi function (Elwell *et al.*, 2011; Derre *et al.*, 2011). CERT, in turn, is linked to ER-associated VapA/B (Figure 1) and sphingomyelin synthases SMS1/2, allowing this multiprotein complex to support sphingomyelin synthesis on the inclusion membrane (Elwell *et al.*, 2011; Derre *et al.*, 2011).

Breaking Free to Avoid Host Cell Killing

It would appear that the simplest strategy to avoid killing via lysosomal antimicrobial responses would be to simply break open a phagosome after uptake and set up a replication niche within the host cell cytosol. This strategy raises complex problems for the pathogen, because in many cell types the presence of cytosolic bacteria stimulates innate immune signaling, which can result in either host cell death, autophagic

clearing of the pathogen, or a robust cytokine response. Therefore, pathogens that follow this strategy must also have the capacity to bypass nonlysosomal antimicrobial responses.

Listeria is a gram-positive rod that enters into the host cytosol shortly after phagocytosis, before the bacterium-containing compartment is able to traffic to the lysosome. *Listeria* appears to interfere with the endocytic Rab5a protein, with the consequence that fusion of the compartment with early endosomes is blocked, potentially preventing maturation of the compartment (Alvarez-Dominguez *et al.*, 2008). The modulation of Rab5a activity may be a consequence of the ADP ribosyltransferase activity of the *Listeria* protein Lmo 2459, which interferes with GDP/GTP exchange by the Rab protein (Alvarez-Dominguez *et al.*, 2008).

The single bacterial protein that is most important for both the intracellular survival of *Listeria* as well as its ability to enter the host cell cytosol is the secreted PFT listeriolysin O (LLO). The activity of the protein is quite pH sensitive with optimal activity observed at approximately pH=5.5, appropriate for a protein that can be activated in an acidic compartment followed by down-modulation in the more neutral cytosolic pH. Other bacterial proteins are also involved in breakdown of the compartment, including the phosphatidylinositol-specific phospholipase C (PI-PLC), and a broad-range phosphatidylcholine phospholipase C (PC-PLC), which is believed to be involved in destruction of the vacuolar double-membranes after the bacterium spreads to neighboring cells (Smith *et al.*, 1995).

The details of vacuole escape by *Shigella* have been more difficult to decipher, and escape may be modulated by proteins whose primary function is to allow movement of proteins from the bacterial cytosol into the host cytosol via a T3SS. These proteins, often called translocon proteins, are inserted into the host cell membrane, forming pores that allow the final step in translocation via the T3SS apparatus. In the case of *Shigella* species, these proteins are IpaB and IpaC, which associate preferentially with cholesterol-rich regions of the membrane (Page *et al.*, 1999; Ferraris *et al.*, 2010). Insertion of these proteins into the host cell is facilitated by another T3SS-translocated protein IpaD (Picking *et al.*, 2005). As *Shigella* encodes a number of phospholipases that are translocated via this system, it is likely that escape from the vacuole is complex, and may involve coordination between the host and the bacterium.

In the case of *Rickettsia* species, the compartment harboring the bacterium appears to be degraded by the action of bacterial phospholipases. The most likely candidate is the secreted phospholipase D (Renesto *et al.*, 2003). In fact, *Salmonella* harboring the gene for this protein encoded by *Rickettsia prowazekii* were able to escape from the replication vacuole (Whitworth *et al.*, 2005). It is believed that lipid substrates of this phospholipase D are found in the compartment, and their depletion by the action of the protein leads to loss of membrane integrity and vacuolar disruption.

Bypass and Exploitation of Host Autophagic Clearing of Microorganisms

One of the primary strategies that host cells utilize to clear cytoplasmically localized pathogens is autophagy. Autophagy was traditionally associated with the ordered engulfment of

cytosolic proteins and organelles that need to be degraded to maintain cellular homeostasis, but it is now clear that this process can also be used to free the cell of unwanted intruders (Christen *et al.*, 2009). In particular, the ubiquitination of either intracellular microbes or the compartments encompassing them are important signals for targeting to the autophagic machinery. As expected, a strategy that allows microbes to survive uptake into host cells is for them to evade autophagic killing. A clever strategy used by *Salmonella* to avoid autophagy is to activate mTOR, a negative regulator of autophagy (Tattoli *et al.*, 2012). The action of mTOR is disrupted if it is removed from endomembranes. In the case of *Salmonella* entry into host cells, the protein gets detached leading to initial inactivation, but the bacterium is able to reverse this effect by recruiting mTOR to the surface of the bacterium-containing vacuole (Tattoli *et al.*, 2012). Although there is significant down-modulation of autophagy, the bacterium uses a second strategy to further bypass this host response. There is ubiquitination of the bacterial compartment, and the *Salmonella* protein SseL deubiquitinates proteins, preventing recognition by host autophagic receptors (Figure 2; Mesquita *et al.*, 2012).

Listeria interferes with autophagy at several levels. The *Listeria* protein ActA allows the cytosol-localized bacterium to move via actin-based motility, and this is important for avoiding recognition by autophagy because mutants lacking this protein get ubiquitinated and cleared by the autophagic machinery (Ogawa *et al.*, 2009). In parallel, the host

autophagic machinery is impaired by *Listeria* phospholipases PI-PLC and PC-PLC, possibly by reducing PI3P levels (Tattoli *et al.*, 2013). Finally, the bacterial surface protein InlK recruits the host's major vault protein (MVP) to the bacterial surface, which interferes with recognition of bacterial cell surface ubiquitination by the host cell autophagic machinery (Dortet *et al.*, 2011; Figure 2).

Shigella faces similar problems to those encountered by *Listeria*, as both organisms are localized in the host cell cytosol and use actin-based motility for cell-to-cell spread. An important host initiator of autophagy, Atg5, binds to the bacterial IcsA protein, which is needed to promote bacterial actin-based motility and spread to other cells. Thus the bacterium is faced with the conundrum of needing to spread via a protein that could target it into a degradative compartment. *Shigella* escapes autophagy by secreting IcsB, which binds IcsA and prevents Atg5 recognition (Ogawa *et al.*, 2011). In addition, the bacterium secretes VirA, a RabGAP protein that inactivates Rab1, a protein important in the formation of autophagosomes (Dong *et al.*, 2012; Zoppino *et al.*, 2010).

It was originally hypothesized that *L. pneumophila* delays autophagy (Amer and Swanson, 2005), and recent evidence agrees with this model. *Legionella pneumophila* translocates a protein, RavZ, which interferes with autophagy by inactivating a key component of this pathway. RavZ irreversibly deconjugates LC3, a critical protein that needs to be linked to the surface of pre-autophagosomal membranes to allow the process of

Figure 2 Modulation of host cell autophagy pathways. (a) Tug of war – *Legionella* both stimulates autophagy and blocks it. Bacterial proteins such as LegA9 cause ubiquitination of the bacterial compartment which could lead to autophagy. The bacterium also translocates RavZ into host cells, which blocks autophagic recognition by deconjugating LC3 from the phagophore. (b) Ubiquitination of *Listeria* is blocked by the bacterial protein ActA. The bacterial InlK protein recruits MVP which interferes with the targeting of the bacterium to the p62 linker protein that directs cargo to the autophagic machinery. (c) *Salmonella* interferes with autophagy by recruiting mTOR to the SCV. The bacterium also encodes a deubiquitinase, SseL, which inhibits autophagy. (d) *Shigella* prevents IcsA from interacting with the autophagy machinery by producing IcsB, which interferes with this interaction. The *Shigella* protein VirA also blocks autophagy by inactivating Rab1. See Asrat *et al.* (2014) for further details.

clearing of cytoplasmic structures to be completed (Choy *et al.*, 2013). A recent report indicated that another *L. pneumophila* protein, LegA9 stimulates recognition of the LCV by the host autophagy machinery, although the role of this recognition during the replication process is unclear (Khweek *et al.*, 2013). LegA9 mutants show less autophagic markers around the replication compartment, indicating that the protein may target the autophagy machinery to the site of bacterial replication (Khweek *et al.*, 2013). A summary of bacterial interactions with the autophagic machinery is displayed in Figure 2.

Bacterial Embrace of Autophagy

Surprisingly, some bacteria actively exploit the autophagic machinery to ensure survival and intracellular growth. The compartment encompassing *Coxiella* is composed of a number of autophagic markers and disruption of autophagy interferes with bacterial growth (Romano *et al.*, 2007). Furthermore, it appears that proteins translocated by the bacteria are required to form this autophagosome-like compartment (Carey *et al.*, 2011). Autophagy may support the growth of *Brucella*, as well (Pizarro-Cerda *et al.*, 1998). The *Brucella* replication compartment is encompassed by an autophagosome, and its formation is dependent on a subset of autophagy proteins, including Beclin-1 (ATG6) (Starr *et al.*, 2012). In addition to aiding growth, there is evidence that cell-to-cell spread of *Brucella* is supported by the formation of these autophagosomes (Starr *et al.*, 2012). Finally, although *Francisella* grows within the cell cytosol, it appears to enter a compartment that has autophagosome-like characteristics late in the infection cycle (Checroun *et al.*, 2006). These compartments stain positive for both late endosomal as well as autophagosomal markers, such as LC3 (Checroun *et al.*, 2006). Once inside this compartment, the bacteria cease to replicate, but they are not killed, thus it is possible that this autophagosomal compartment supports bacterial egress from the host cell.

Perspective

Phagocytic attack is the initial strategy that allows a host to battle against invading microorganisms. Therefore, being able to survive this attack is a primary determinant of whether a microbe is able to cause disease. The primary strategies that microbes use to combat the phagocyte are to kill the cell, prevent phagocytosis, or promote survival within an intracellular niche after phagocytosis. There are clearly a number of ways in which pathogenic bacteria can follow each of these strategies, and the approach taken by each is an important factor that defines the nature of the disease that occurs in the host. Studying how pathogens subvert and manipulate the host cell has contributed greatly to our understanding of a number of cell biological processes and has allowed detailed dissection of how pathogens cause disease at the molecular level.

Introduction

Bacterial pathogens evolved similar traits to manipulate host cell functions for their own benefit and to evade or manipulate the host immune system. The ability to invade cells and live intracellularly is one of these strategies developed in a process of coevolution between the bacteria and the host. Unlike the process of phagocytosis, in which a microbe is engulfed by professional phagocytic cells, invasion refers to the entry process whereby a microbe actively triggers its own uptake by non-phagocytic cells. Depending on their capacity to survive and replicate outside their host, invasive bacteria can be obligate intracellular organisms, like *Rickettsia* spp. or *Chlamydia* spp., or facultative intracellular organisms, like *Salmonella* spp., *Shigella* spp., or *Listeria monocytogenes*. For all these bacteria, however, invasion is a feature of their pathogenesis. On the other hand, an increasing number of bacteria which are generally considered exclusively extracellular can be found in some circumstances inside several types of cells, a feature which has been linked to their capacity for persistence and their pathogenesis (Schwarz-Linek *et al.*, 2006). Some examples of this last group are *Streptococcus pyogenes* and *Staphylococcus aureus*.

In a general way, the invasion process involves four main stages: entry, survival, replication, and exit or spreading. Pathogenic invasive bacteria enter cells by binding to host plasma membrane receptors or injecting bacterial proteins and promoting their uptake by actin remodeling. Once inside, they either transform the internalization vacuole into a replicative niche by manipulating its maturation, adapt to the intravacuolar environment, or they escape from the vacuole and adopt a cytoplasmic lifestyle. During the infectious process,

they develop mechanisms to avoid killing by cellular innate immunity and to manipulate inflammatory responses, cell survival pathways, autophagy, or intracellular trafficking.

Entry Mechanisms

The invasion mechanisms are historically classified based on two main morphological rearrangements of the host plasma membrane, as it was firstly proposed for the general phagocytic process. In the first mechanism, called the 'zipper mechanism,' bacterial surface molecules, generally called adhesins, bind to host plasma membrane receptors with high affinity to trigger the intracellular signaling needed for their uptake. The host cell receptors are typically transmembrane adhesion molecules involved in cell-to-cell or cell-extracellular matrix interactions. During this entry process, the cell membrane tightly surrounds the bacteria while undergoing subtle cytoskeleton rearrangements (Figure 1(a)). The second mechanism is called the 'trigger mechanism,' in which bacteria use a type III secretion system (TTSS) to inject virulence proteins, or effectors, into the host plasma membrane and cytoplasm, triggering massive actin polymerization, with membrane ruffling and filopodia forming the entry focus (Figure 1(b)).

Despite the differences between these two entry mechanisms, three common events can be distinguished: (1) contact with the host cell, (2) induction of actin remodeling and formation of an internalization vacuole, and (3) actin depolymerization and vacuole closure.

These mechanisms will be described in detail in the following sections.

Figure 1 Mechanisms of bacterial invasion. (a) The 'zipper mechanism.' Scanning electron micrograph of *L. monocytogenes* entering into epithelial cells. Zipper

The best-known examples of bacteria using the zipper entry process are the enteropathogens *L. monocytogenes*, *Yersinia pseudotuberculosis*, and *Yersinia enterocolitica*. These bacteria evolved a similar mechanism to induce their uptake, yet with some variations in the molecular machineries involved in the process.

The *Y. pseudotuberculosis* adhesin, called invasins, was the first bacterial adhesion molecule identified to bind a host mammalian receptor, the $\beta 1$ chain of integrins (Isberg and Leong, 1990). Though *Yersinia* is able to impair its uptake by phagocytic cells through the injection of antiphagocytic effectors by its TTSS, it is able to invade epithelial cells using invasins during the first steps of infection whereby the bacteria traverse the intestinal epithelial lining. Invasins mimics fibronectin binding to the adhesion molecule $\beta 1$ -integrin but with higher affinity, inducing receptor clustering that triggers the downstream integrin signaling cascade. Thereby, *Yersinia* entry involves the repertoire of kinases and adaptor proteins participating in focal adhesion dynamics, such as focal adhesion kinase (FAK), Src, Pyk2, Cas, and Crk, with the consequent activation of the RhoGTPase Rac1, which directs Arp2/3-mediated cytoskeleton remodeling around the bacteria (Wong and Isberg, 2005).

Yersinia pseudotuberculosis can also enter cells through another adhesin, YadA, presumably after crossing the intestinal epithelium and in cases where invasins expression is repressed. This adhesin, unlike invasins, binds proteins from the extracellular matrix that in turn bind to host cell $\beta 1$ -integrins (Heise and Dersch, 2006). A similar strategy is used by the two facultative invasive pathogens, *S. pyogenes* and *S. aureus*, which express fibronectin-binding proteins on their cell wall that permit cellular invasion. Notably, the resulting intracellular signaling cascade is similar to the one induced by *Yersinia* invasins (Schwarz-Linek et al., 2006).

In the case of *L. monocytogenes*, two adhesins harboring leucine-rich repeats were described as mediators of invasion, each of them binding to different host receptors: internalin A (InlA) and internalin B (InlB). InlA is a bacterial membrane-attached protein that binds the extracellular domain of the host adherens junction adhesion molecule E-cadherin (Menga et al., 1996). InlB, on the other hand, is a loosely attached surface protein that induces the invasion of cells mainly by interaction with the extracellular domain of the Met receptor tyrosine kinase, the receptor for the hepatocyte growth factor (HGF) (Shen et al., 2000). *In vivo*, InlA-mediated invasion is restricted to cells expressing E-cadherin and is responsible for translocation across the intestinal epithelium barrier, whereas InlB is necessary, in conjunction with InlA, for translocation across the placenta (Disson et al., 2008).

Listeria monocytogenes entry through InlA mimics the signaling induced in adherens junctions formation. For example, both processes are dependent on binding of the cytoplasmic domain of E-cadherin to β -catenin and α -catenin, and involve myosin VII and the surface molecule vezatin, molecules bridging adherens junctions with the actin cytoskeleton and with motor proteins (Pizarro-Cerdá and Cossart, 2009). ARHGAP10, a Cdc42/Rho guanine-activating protein (GAP), is involved in α -catenin recruitment to adherens junctions and also plays a role during infection (Sousa et al., 2005). As ARHGAP10 binds also Arf6, which in turn interacts

with vezatin, it was proposed that Arf6 could mediate the coupling between the tracking force exerted by myosin VIIA and adherens junctions (Sousa et al., 2005; Figure 2(a)).

Conversely, InlB phenocopies the HGF-induced signaling cascade, inducing Met receptor dimerization, autophosphorylation of the cytoplasmic domain, and the recruitment and phosphorylation of several adaptors, such as Cbl, Gab1, CrkII, and Shc, with the ensuing activation of phosphatidylinositol (PI)-3-kinase (PI3K) (Dokainish et al., 2007; Pizarro-Cerdá and Cossart, 2009; Figure 2(b)).

In both entry pathways, an Arp2/3-dependent local actin polymerization takes place. In the case of InlA-mediated entry, the process is initiated by Src kinase activation, which in turn phosphorylates cortactin. Rac1 is also involved in this entry mechanism. In InlB-mediated entry, on the other hand, this event is triggered by PI3K activation. PI3K induces PI(3,4,5)P₃ production at the entry site and the local activation of Rac1/Cdc42, with the ensuing recruitment of N-WASP/WAVE (Sousa et al., 2007; Pizarro-Cerdá and Cossart, 2009). Src also phosphorylates the cytoplasmic domain of E-cadherin, inducing its subsequent ubiquitination by Hakai ubiquitin ligase (Bonazzi et al., 2008).

Interestingly, the ubiquitination of E-cadherin by Hakai and that of Met and $\beta 1$ -integrin by Cbl ubiquitin ligases, respectively, induces the recruitment of clathrin to the site of entry, with the participation of dynamin-2 and noncanonical clathrin adaptors. This recruitment happens upstream of actin polymerization, and also appears to be induced by *S. aureus* (Veiga et al., 2007). However, it is still not clear whether clathrin is involved directly in the engulfment of the bacteria or rather serves as a signaling platform for the recruitment of the actin machinery. Moreover, caveolin-1, the main component of plasmalemmal caveolae, is important for E-cadherin clustering and InlA-bacterial entry (Bonazzi et al., 2008). Thus, several types of endocytic machineries seem to be involved in *L. monocytogenes* entry.

Closure and scission of the internalization vacuole formed during *Yersinia* invasion involve several steps, including the activation of PI-4-phosphate-5-kinase (PIP5K) by Rac1 and Arf6, inducing localized PI(4,5)P₂ production, and subsequent PI(4,5)P₂ consumption by PI3K and the 5-phosphatases OCRL1 and Inpp5b, which are recruited in a Rab5-dependent manner (Sarantis et al., 2012). Similarly, the last step in *L. monocytogenes* invasion is mediated by the fine regulation of cofilin activity by LIM-kinase, and by OCRL1. Actin depolymerization by cofilin and the consumption of PI(4,5)P₂ by OCRL1 and PI3K help the scission process (Pizarro-Cerdá et al., 2015).

Another example of bacteria invading host cells through the zipper mechanism is provided by Rickettsiae, which attach to the host receptor Ku70 on endothelial cells via the surface protein OmpB, inducing an intracellular signaling cascade and bacterial uptake in a way similar to *L. monocytogenes* and *Yersinia* spp. (Martinez et al., 2005).

Trigger

Salmonella, *Shigella*, and *Chlamydia* use a TTSS to inject effectors into the host cell in order to trigger their uptake. The TTSS molecular machinery comprises a cytoplasmic domain, a basal

Figure 2 Signaling pathways triggered by bacterial invasion. (a) *Listeria monocytogenes* InlA-mediated entry. Inl A interacts with E-cadherin, mimicking the signaling induced in adherens junctions formation. E-cadherin cytoplasmic domain binds β -catenin and α -catenin, which recruits ARHGAP10, vezatin, and myosin VII. Arf6 interacts with ARHGAP10 and vezatin, bridging adherens junctions with actin cytoskeleton. Caveolin is involved in Src activation. Activated Src phosphorylates E-cadherin, inducing subsequent ubiquitination by Hakai and clathrin recruitment. Src also phosphorylates cortactin, inducing Arp2/3-dependent actin polymerization. Rac1 is also activated inducing actin dynamics. (b) *Listeria monocytogenes* InlB-mediated entry. InlB binds and induces activation of Met receptor. The intracellular signaling cascade involves phosphorylation and ubiquitination of Met, which recruits clathrin; recruitment and phosphorylation of adaptors such as Cbl, Shc, Gab, and Crkl; and activation of PI3K, which triggers Rac1/Cdc42 activation and Arp2/3-dependent actin polymerization. (c) *Shigella* invasion. *Shigella* injected effectors target host RhoGTPases and kinases triggering massive actin polymerization. Cortactin activation occurs downstream of Src activation by IpaC. IpgB1 and IpgB2 activate Cdc42, Rac1, and RhoA GTPases. IpgD converts PIP2 into PI5P, inducing cortical actin dissociation from plasma membrane. IpaA binds the focal adhesion protein vinculin, promoting actin remodeling and disassembly. (d) *Salmonella* 'trigger' mechanism. Similar to *Shigella*, *Salmonella* injects effectors inducing its uptake. SopE and SopE2 are RhoGEF, activating Cdc42 and Rac1. SipA inhibits cofilin, stabilizing actin filaments. SipC is an actin nucleator and crosslinker of actin filaments. SopB is a PI phosphatase that can activate RhoG, and induces ARNO/Arf GEF activation, WAVE activation, and Arp2/3-dependent actin polymerization. SptP is a RhoGAP that counteracts SopE/E2 RhoGEF activities, inducing actin disassembly.

body, a needle-like structure, and the translocator complex, the latter forming a pore in the plasma membrane of the target cells to allow effector injection (Cornelis, 2010). *Shigella* and *Chlamydia* possess one TTSS encoded on a large virulence plasmid and on the chromosome, respectively. *Salmonella*, on the other hand, has two TTSS encoded on two different genomic *Salmonella* pathogenicity islands (SPI): SPI-1 and SPI-2. TTSS assembly and activation are initiated by environmental

stimuli such as temperature, pH, oxygen tension, bile salts, and contact with the target cell.

Bacterial attachment

The first interaction with the cell can be accomplished by different means. *Chlamydia*, for example, has no identified adhesin. However, the PDGF-receptor β , heparan sulfate glycosaminoglycans, and protein disulfide isomerase on the

target cell surface are involved in the attachment of chlamydial elementary bodies (EBs) (Bastidas *et al.*, 2013). The EB is the non-replicative, infectious form of the bacteria, in contrast to the reticular body (RB), which is the intracellular and replicative form.

For *Shigella*, two distinct mechanisms of adhesion to epithelial cells have been described. Firstly, bile salts in the intestinal lumen can induce adhesion in a TTSS-dependent manner, promoting the attachment via polar IcsA (Zumsteg *et al.*, 2014). Second, the interaction can occur between the tip of the TTSS and a cell surface receptor present in the filopodia, followed by subsequent filopodia retraction, bringing bacteria close to the cell body (Romero *et al.*, 2011).

On the other hand, *Salmonella*, which is a flagellated bacterium, possesses several fimbriae and adhesins that interact with cells in addition to the SPI-1 TTSS, which induces an irreversible interaction with the host membrane (Lara-Tejero and Galán, 2009). A 'near surface swimming' model proposes that *Salmonella* swims by flagellar movement to scan the host surface topology, docking at sites of prominent topology by irreversible SPI-1 TTSS-mediated interaction, thereby explaining the site selection and the cooperative infection (Misselwitz *et al.*, 2012). Bacterial docking to the membrane allows the assembly of the translocation complex, activating the coordinated secretion of prestored cytosolic TTSS invasion effectors.

Activation of secretion

The proteins forming the translocon of the TTSS are IpaB/IpaC in *Shigella* and their homologs SipB/SipC in *Salmonella*. Plasma membrane cholesterol and lipid microdomains are important for translocon assembly and activation. IpaB and SipB, for example, interact directly with cholesterol. The TTSS activation may occur by induction of architectural changes in the needle that allow the assembly of the translocon and the initiation of injection, and/or through the local enrichment of receptors important for entry (Lafont and van der Goot, 2005). Moreover, *Salmonella* invasion is enhanced, in a SipB-dependent manner, in mitotic cells due to the cholesterol enrichment in the outer leaflet of the plasma membrane during mitosis (Santos *et al.*, 2013). However, there are contradictory reports regarding this topic (Gilk *et al.*, 2013) and its *in vivo* relevance remains unclear.

Actin and membrane rearrangement

Rearrangement of the actin cytoskeleton and formation of membrane protrusions are induced by TTSS-injected effectors that manipulate, either directly or indirectly, the main regulators of these processes: RhoGTPases, phosphoinositides, and tyrosine kinases. *Shigella* IpgB1 and IpgB2 effectors, for example, are guanine nucleotide exchange factors (GEFs) for Cdc42/Rac1 and RhoA, respectively (Huang *et al.*, 2009), but IpgB1 can also activate Rac1 through the recruitment of the ELMO/Dock180 machinery (Handa *et al.*, 2007). As a result, Rac1 activation induces downstream Arp2/3-dependent actin polymerization and ruffling, whereas RhoA induces stress fiber formation. IpgB2 activity, in conjunction with the other Rho-activating effector IpaA, might promote bacterial anchorage (Carayol and Tran Van Nhieu, 2013). The IpaC C-terminal domain, on the other hand, recruits and activates Src, which in turn phosphorylates cortactin, amplifying actin polymerization (Mounier

et al., 2009). IpaC also induces activation of Rac1/Cdc42, which is probably mediated by Src-Crk or through Abl kinase activity, another kinase activated during the invasion process (Carayol and Tran Van Nhieu, 2013; Schroeder and Hilbi, 2008). Actin remodeling is enhanced by the PI-phosphatase IpgD. This effector converts PI(4,5)P₂ into PI5P and leads to the dissociation of the plasma membrane from the actin cytoskeleton (Niebuhr *et al.*, 2002; Figure 2(c)).

For *Salmonella*, five effectors secreted by the SPI-1 TTSS are critical for entry. SipC and SipA interact directly with actin: SipC nucleates actin and crosslinks actin filaments, and SipA stabilizes the latter and inhibits cofilin. The bacteria also secrete two RhoGEFs, SopE and SopE2. They activate Rac1 and Cdc42, inducing the branching of actin filaments in an Arp2/3-dependent process (Patel and Galán, 2006; Ly and Casanova, 2007). SopB, which is a pleiotropic PI phosphatase, consumes PI(4,5)P₂ at the plasma membrane, leading to the same effect than its homologous IpgD. Additionally, SopB induces PI3P production and can indirectly activate RhoG through the SH3-containing GEF (Patel and Galán, 2006). Local production of PI3P also induces ARNO/Arf GEF recruitment, which in turn activates Arf. WAVE, which is recruited by SopE, is further activated by Arf and Rac1, finally triggering actin polymerization (Humphreys *et al.*, 2012; Figure 2(d)).

SipC recruits to the plasma membrane the exocyst complex component Exo70, promoting the docking and fusion of exocytic vesicles. Exocyst complex activation is mediated by RalA GTPase via SopE (Nichols and Casanova, 2010). This process stimulates membrane expansion at the bacterial entry site.

For *Chlamydia trachomatis* the injected effector TARP is the only one so far with known functions in bacterial entry: it is an actin nucleator (Jewett *et al.*, 2006) and, through phosphorylation by Src/Abl kinases, binds host proteins involved in Arp2/3-dependent actin remodeling such as Rac1, Rac1-GEFs, WAVE2, and PI3K (Lane *et al.*, 2008). Rac1 activation is critical for *C. trachomatis* entry; however, TARP phosphorylation is not essential, meaning that Rac1 can be activated by an additional and yet uncharacterized mechanism (Bastidas *et al.*, 2013; Dumoux *et al.*, 2014).

Actin depolymerization and vacuole closure

The disassembly of actin filaments and the end of the entry process is promoted in *Shigella* by the effector IpaA, which binds the focal adhesion protein vinculin (Carayol and Tran Van Nhieu, 2013; Figure 2(c)). The *Chlamydia* effector CT694 may perform a similar function (Bastidas *et al.*, 2013). The *Salmonella* PI-phosphatase SopB induces PI(4,5)P₂ consumption, which is critical for membrane fission during vacuole closure (Terebiznik *et al.*, 2002). Furthermore, the effector SptP is a GAP for RhoGTPases, counteracting SopE/E2 RhoGEF activities (Figure 2(d)). The sequential activity of SopE and SptP has been suggested to be regulated by differential half-life or secretion rates (Van Engelenburg and Palmer, 2008; Kubori and Galán, 2003).

It should be noted that even if we distinguish two general entry mechanisms, there is increasing evidence suggesting more than one entry mechanism for some bacteria. *Salmonella*, for example, can also enter cells by an Arp2/3-independent mechanism whereby SopB activates RhoA and the downstream effector Rho kinase to induce a myosin II, contractility-dependent

pathway (Hänisch *et al.*, 2011). In addition, the *Salmonella* proteins Rck and PagN are involved in TTSS-independent, zipper-like entry mechanisms (Velge *et al.*, 2012). Another example is *Chlamydia* (Dumoux *et al.*, 2014), which injects protein effectors that remodel the actin cytoskeleton. At the same time, it was proposed that the clathrin machinery is important for *Chlamydia* entry (Hybiske and Stephens, 2007). Furthermore, *Chlamydia* binds and activates PDGF-receptor β (Bastidas *et al.*, 2013). Both clathrin-mediated entry and receptor binding constitute features generally proposed to be part of the zipper mechanism (Veiga *et al.*, 2007).

Intracellular Lifestyle and Manipulation of Host Intracellular Trafficking

Invasive pathogenic bacteria have evolved mechanisms to survive inside cells after internalization into a primary vacuole. The great majority are able to live and replicate inside a pathogen-containing vacuole, either by blocking vacuole maturation or by adapting to harsh intravacuolar conditions (Kumar and Valdivia, 2009). However, some intracellular bacteria escape from the vacuole to the host cell cytoplasm, which is thought to be a richer source of nutrients than vacuoles and devoid of the antimicrobial mechanisms of phagosomes (Ray *et al.*, 2009). Despite the apparently safer conditions, the cytoplasm contains a range of antimicrobial, autophagic, and inflammatory factors that cytoplasmic bacteria need to avoid in order to survive. Indeed, the cytoplasm has been shown to be nonpermissive for replication of a variety of intravacuolar bacteria (Ray *et al.*, 2009).

Interestingly, whether invasive bacteria are vacuole-dwelling or live in the cytosol is independent from the mechanism of entry and from the property of being obligate or facultative intracellular bacteria (Casadevall, 2008). For example, both *Shigella* and *Salmonella* use the trigger mechanism to invade target cells, but *Shigella* lyses the vacuole and escapes to the cytoplasm, while *Salmonella* stays inside a *Salmonella*-containing vacuole (SCV). *Listeria monocytogenes*, on the other hand, uses the zipper mechanism for its entry but, just as *Shigella*, lyses the vacuole and moves into the cytosol using actin-based motility (ABM). In addition, obligate intracellular bacteria such as *Rickettsia* escape into the cytosol, while other obligate intracellular pathogens like *Coxiella* or *Chlamydia* remain in a vacuolar compartment (Figure 3).

Intravacuolar Bacteria

Bacteria inhabiting a vacuolar compartment hijack host membrane trafficking pathways not only to avoid the cellular immune response, but also to acquire nutrients for their replication, and membrane to enlarge their vacuole. Vacuole maturation and integrity are regulated by the interplay between several factors, such as the cytoskeletal network of microtubules, actin and associated motor proteins, the lipid composition of the vacuole, host GTPases as well as bacterial effectors, which tightly regulate these processes for their own benefit (Figure 4).

After internalization, *Salmonella* manipulates the host endolysosomal pathway to establish the SCV as a replicative

(a)

(b)

(c)

Figure 3 Bacterial intracellular lifestyles. (a) Fluorescence microscopy of *Shigella* ABM (red: actin; green: bacteria). (c) Fluorescence microscopy of Golgi fragmentation and recycling endosomes tubulation induced by *Shigella* invasion. Inset, noninfected cell (gray: bacteria; green: GM130, Golgi marker; red: transferrin, recycling endosomes).

Figure 4 Schematic representation of bacterial intracellular lifestyles and manipulation of host intracellular trafficking. *Shigella* and *L. monocytogenes* lyse the vacuole after entry and move into the cytosol by ABM. *Shigella* vacuolar escape is mediated by the translocon protein IpaB, and is enhanced by the IpgD-dependent recruitment of Rab11 endosomes. *Shigella* effector IpaJ targets Arf1 inducing Golgi fragmentation, whereas VirA inactivates Rab1 blocking ER–Golgi transport. *Listeria monocytogenes* induces vacuolar disruption by secretion of the pore-forming toxin listeriolysin O (LLO). *Listeria monocytogenes* InlC protein promotes bacteria spreading to adjacent cells. *Chlamydia* and *Salmonella* remain in a vacuolar compartment, the *Chlamydia* inclusion and the SCV, respectively, which acquire different protein and lipid markers. *Salmonella* SipC recruits Exo70 to the entry site, promoting the docking and fusion of exocytic vesicles. SifA inhibits retrograde trafficking of MPR, attenuating lysosome function. Chol, cholesterol; EB, elementary body; EE, early endosomes; ER, endoplasmic reticulum; LE, late endosomes; RB, reticular body; RE, recycling endosomes; SM, sphingomyelin.

niche. First, the SCV acquires early endosomal markers such as early endosomal antigen 1 (EEA1), transferrin receptor (TfR), and Rab5. Then, the SCV matures to a vATPase- and LAMP1-positive compartment, in a Rab7-dependent mechanism (Malik-Kale *et al.*, 2011). The manipulation of RabGTPase dynamics during SCV maturation is dependent on the PI-phosphatase activity of SopB, which regulates the PI surface content on the SCV and consequently the negative charge of the SCV membrane, thereby regulating the recruitment and detachment of RabGTPases (Pizarro-Cerdá *et al.*, 2015). In addition, SifA blocks Rab9-dependent mannose-6-phosphate receptor (MPR) retrograde traffic, thereby affecting lysosomal maturation and avoiding the acquisition of lysosomal hydrolases by the SCV (McGourty *et al.*, 2012). During the maturation process, the SCV moves toward the microtubule organizing center (MTOC) and the peri-Golgi region (Salcedo and Holden, 2003), and develops *Salmonella*-induced filaments (Sifs), which expand to the cell periphery. These

processes are dependent on interactions with the cytoskeleton and dynein–kinesin motors and on the activity of several bacterial effectors, including SifA. A network of F-actin surrounds the SCV and provides structural stability; thus, its depolymerization induces loss of SCV integrity (Malik-Kale *et al.*, 2011). Sifs interact also with the Golgi apparatus owing to SPI-2 TTSS effectors, probably to acquire nutrients and lipids from the secretory pathway that are important for bacterial replication and vacuole enlargement or as a strategy to manipulate host immunity (Mota *et al.*, 2009). Interestingly, cholesterol is excluded from the SCV by the enzymatic activity of the SseJ effector, modifying the SCV membrane properties and allowing Sif formation (Lossi *et al.*, 2008).

Similarly, the *Chlamydia*-containing vacuole, called inclusion (Figure 3(b)), moves to the MTOC using dynein (Grieshaber *et al.*, 2003), but without acquiring endolysosomal markers. This large and rigid organelle interacts with components from the Golgi apparatus, lipid droplets,

multivesicular bodies, and mitochondria to efficiently acquire a large variety of nutrients and polar lipids, cholesterol, and sphingomyelin (Bastidas *et al.*, 2013). In addition, F-actin forms a structural scaffold with intermediate filaments around the *Chlamydia* inclusion (Kumar and Valdivia, 2008). Several Rabs interact with the inclusion, including Rab 4, 11, and 14 that are involved in receptor recycling, and Rab 1 and 6, which are implicated in endoplasmic reticulum (ER)–Golgi transport. Remarkably, *Chlamydia* infection induces Golgi fragmentation into mini-stacks that surround the inclusion (Heuer *et al.*, 2008) in a process regulated by Rab6 and Rab11 (Rejman Lipinski *et al.*, 2009), but independent of *Chlamydia* CFAP protease activity (Snaveley *et al.*, 2014), as previously suggested (Heuer *et al.*, 2008). Other important recruited factors are proteins involved in PI4P production, such as OCRL1, Arf1, and its downstream interactor PI4KII α , all of which are critical for inclusion growth (Bastidas *et al.*, 2013). Furthermore, *Chlamydia* secretes TTSS effectors, particularly the Inc proteins, which localize extensively to the inclusion membrane. These effectors are involved in diverse functions including Rab recruitment, inclusion biogenesis, homotypic fusion of the inclusion, and sphingomyelin acquisition (Bastidas *et al.*, 2013).

Occasionally, intravacuolar bacteria escape into the cytosol where they can replicate. In the case of *Salmonella*, for example, this event is accompanied with epithelial cell extrusion and may be a strategy for bacterial dissemination (Knodler *et al.*, 2010).

Cytosolic Bacteria

Bacteria from this group are able to escape from the internalization vacuole, replicate in the cytosol, and avoid cytosolic innate immunity for their further dissemination (Figure 4).

The escape from the vacuole is a very fast process driven by secreted bacterial factors. *Listeria monocytogenes* uses the pore-forming toxin listeriolysin O (LLO) and type C phospholipases (PLC). LLO is a thiol-activated and cholesterol-dependent toxin that, after activation by the acidic conditions of the maturing vacuole, inserts into the membrane to form large pores that inhibit vacuole maturation (Pizarro-Cerdá and Cossart, 2009). Vacuolar disruption is further promoted by PLCs, which destabilize the enclosing membrane. *Rickettsia* spp. also express phospholipases and haemolysin C that are probably involved in bacterial escape (Ray *et al.*, 2009).

On the other hand, the *Shigella* TTSS effector IpaB is required for vacuole escape in macrophages (High *et al.*, 1992), likely due to the formation of the bacterial translocon together with the effector IpaC. However, as IpaB/IpaC are essential to invasion, it is experimentally challenging to confirm this function in epithelial cells. It has been proposed that other effectors encoded in the bacterial virulence plasmid but not essential for the entry may promote vacuole rupture (Mellouk *et al.*, 2014; Ray *et al.*, 2009; Schroeder and Hilbi, 2008).

Once in the cytoplasm, bacteria replicate and move in the cytosol by actin-based motility. They express proteins at one pole that induce the polymerization of actin to form actin comet tails (Figure 3(a)). This propels bacteria toward the cell periphery and promotes cell-to-cell spread by induction of protrusions into adjacent cells. *Listeria monocytogenes* ActA mimics N-WASP, directly activating Arp2/3 complex; *Shigella*

IcsA, instead, binds N-WASP to recruit the Arp2/3 complex thereafter. In both cases bacteria promote the polymerization of branched-actin filaments (Iretton, 2013). Interestingly, *Rickettsia* have a slow motility at early times of infection that is driven by RickA and Arp2/3, while at later times it uses Sca2 to mimic formins, thereby inducing long, unbranched actin filaments (Reed *et al.*, 2014).

Membrane protrusions penetrate neighboring cells forming double membrane vacuoles that are lysed through the activity of bacterial and also host factors. In *Shigella*, this process is dependent on the reactivation of the TTSS (Campbell-Valois *et al.*, 2014) and on host motor proteins, adhesion molecules, and a noncanonical clathrin endocytic pathway exploited at tricellular junctions in the neighboring cell (Fukumatsu *et al.*, 2012). *Listeria monocytogenes* secretes InlC after invasion, which promotes formation of protrusions by disrupting complexes between the host proteins TUBA and N-WASP, which generate tension at tight junctions. Hence *L. monocytogenes* may use InlC to decrease membrane tension and promote spreading (Rajabian *et al.*, 2009).

It is interesting to note that cytosolic bacteria, just as vacuole-dwelling pathogens, are able to alter the intracellular trafficking pathways of the host cell (Figure 4). Since cytosolic bacteria already have access to nutrients, targeting trafficking pathways may provide them another kind of benefit. *Shigella*, for instance, recruits Rab11 endosomes to the entry site just after actin focus formation. This recruitment is dependent on the TTSS effector IpgD and enhances bacterial vacuolar escape (Mellouk *et al.*, 2014). Moreover, IpgD activity subverts endocytosis and signaling downstream of the EGF receptor, promoting host cell survival (Ramel *et al.*, 2011). After invasion, *Shigella* induces fragmentation of the Golgi apparatus *in vitro* and *in vivo*, and causes recycling endosome tubulation, thereby blocking TfR recycling and cell secretion (Mounier *et al.*, 2012; Figure 3(c)). IpaJ, a cysteine protease, cleaves the Arf1 N-myristoyl modification inducing Arf1 detachment from the Golgi and thereby its fragmentation (Burnaevskiy *et al.*, 2013). In addition, VirA, blocks ER–Golgi trafficking through its RabGAP activity, leading to Rab1 inactivation. It was also proposed that the VirA GAP activity mediates bacterial escape from autophagy (Dong *et al.*, 2012). On the other hand, soon after entry of *L. monocytogenes* into macrophages, the protein Lmo2459 inhibits Rab5a activation, which indirectly activates the bactericidal NADPH (nicotinamide adenine dinucleotide phosphate) oxidase at the vacuolar surface (Pizarro-Cerdá and Cossart, 2009).

Cellular Responses to Bacterial Invasion

Cellular innate immune defenses are triggered by extracellular or intracellular receptors in response to pathogen-associated molecular patterns (PAMPs) or pathogen-induced host cell danger-associated molecular patterns (DAMPs). Signaling induced by these different molecular patterns can lead to the activation of pathways involved in inflammatory responses, autophagic degradation, or cell death. However, invasive bacteria have evolved strategies to avoid or manipulate these pathways. A few examples of these mechanisms are mentioned below.

Autophagy

The *Shigella* IcsA protein is not only the bacterial factor responsible for ABM, but is also recognized by the Atg5 autophagy protein. It was proposed, however, that the *Shigella* TTSS effector IcsB binds IcsA and blocks its binding to Atg5, thus impairing autophagy (Ogawa *et al.*, 2005). This mechanism may function in addition to the VirA-mediated escape from autophagy through Rab1 inactivation mentioned before (Dong *et al.*, 2012). *Listeria monocytogenes* ActA, on the other hand, directly masks autophagic recognition through Arp2/3 recruitment (Yoshikawa *et al.*, 2009) and prevents ubiquitination of bacteria. *Listeria monocytogenes* InlK binds the major vault protein, which also shelters bacteria from recognition by the autophagic machinery (Dortet *et al.*, 2011).

Coxiella burnetii and *Brucella abortus*, on the other hand, are examples of intravacuolar bacteria manipulating autophagy for their own benefit (Kumar and Valdivia, 2009). *Coxiella burnetii* is an extreme case of a pathogen adapted to live and replicate in a parasitophorous vacuole, which is an autophagolysosome-like acidic compartment. The *Brucella*-containing vacuole matures into a vacuole with ER markers and some autophagy-initiation markers. In both cases, stimulation of autophagy increases bacterial replication.

Inflammatory Response

Shigella provides some excellent examples of inflammation modulation. For example, *Shigella flexneri* regulates, both *in vitro* and *in vivo*, the epithelial release of ATP, which is a proinflammatory danger signal upstream of cytokine production. ATP is released during infection with *Shigella*, *Salmonella*, and enteropathogenic *Escherichia coli* (EPEC) through opening of connexin hemichannels. However, the *Shigella* IpgD induces hemichannel closure through its PI phosphatase activity, thereby blocking ATP release and dampening tissue inflammation (Puhar *et al.*, 2013). Another interesting strategy is the ability developed by *Shigella* to remodel its lipopolysaccharide (LPS), the prototypical bacterial PAMP. Intracellular replicating bacteria have a hypoacylated version of the lipid A of the LPS, lowering immune recognition and inflammasome activation (Paciello *et al.*, 2013). Finally, *Shigella* secretes several TTSS effectors, in general with enzymatic activities, that directly target MAP-kinase and NF- κ B signaling, thereby counteracting the inflammatory response stimulated by Nod1 receptor recognition of bacterial peptidoglycan (PGN). These effectors are OspF, a phosphothreonine lyase inactivating p38 and Erk2 MAPKs; IpaH9.8, an E3 ligase targeting the NEMO complex and inducing its proteasomal degradation; OspG, which interferes with I κ B α ubiquitination; OspZ, which blocks nuclear translocation of NF- κ B; and finally OspI that deamidates the E2 enzyme required for TRAF6-NF- κ B signaling (Ashida *et al.*, 2011).

Cell Survival

Bacteria can manipulate cell apoptosis as a strategy for promoting not only host cell survival but also its own. The *Shigella* VirA effector, for example, induces p53 degradation by calpain activation at early times of infection, thus blocking the NF- κ B-

p53 proapoptotic signaling pathway (Bergounioux *et al.*, 2012). IpgD-mediated production of PI5P, on the other hand, subverts the endocytic machinery and growth factor receptor activation to induce activation of the PI3-kinase/Akt survival pathway (Pizarro-Cerdá *et al.*, 2015).

Finally, *Shigella* OspE binds to integrin-linked kinase, stabilizing focal adhesion and reinforcing epithelial cell adhesion to the extracellular matrix, as a strategy to prevent rapid cell turnover and protect its replicative niche (Kim *et al.*, 2009).

Concluding Remarks

Invasive bacteria are capable of exploiting the host cell cytoskeleton and many signaling pathways to enter non-phagocytic cells. Whether induced by receptor binding and activation or by injection of bacterial effectors, bacterial uptake by the target cell requires remodeling of the cytoskeleton and the plasma membrane at the entry site, especially in the case of *Salmonella* and *Shigella*. This is achieved by biochemical changes in the lipid composition of membranes and by protein recruitment that will induce changes in fluidity as well as membrane tension to favor bacterial entry. The downstream signaling events or their manipulation help the establishment of a vacuolar niche and the cross talk between factors inducing vacuole stability, as the vacuolar membrane and host cytoskeleton are constantly remodeled to maintain the biochemical and biophysical properties needed for bacterial proliferation.

Vacuolar remodeling occurs also during infection with cytosolic bacteria, but, in contrast to what happens with vacuolar pathogens, leads to vacuolar rupture and bacterial escape. Host kinases and small GTPases from the Rho and Rab families are key host factors that pathogens manipulate to orchestrate each of these steps. Remarkably, invasive bacteria evolved sophisticated strategies to avoid immune responses. In conclusion, pathogen–host coevolution resulted in several traits acquired by pathogenic bacteria to manipulate each of the important factors that are critical for a successful invasion.

Introduction

Pathogenic bacteria produce a large variety of protein toxins to increase their chance of multiplication within their hosts and/or to promote their diffusion. These toxins are the result of the coevolution of microorganisms and hosts, which select microbial products capable of subverting the host's physiology to the benefit of the producing bacteria. The 'preferred' targets of bacterial toxins are components of the host immune system, including immune cells and complement proteins, and the epithelial barrier, but several other host functions and cells are also targeted.

The understanding of the structure and function of bacterial toxins has allowed the development of vaccines, antibodies, and other therapeutics aimed at preventing or curing the diseases caused by the toxins. In addition, toxins have proven to be valuable tools for the dissection of several physiological processes of the cell. This review aims at describing the activity and use of bacterial toxins in cell biology.

Bacterial toxins can act: (1) on the cell surface (pore-forming toxins (PFT), sphingomyelinases, phospholipases, superantigens, etc.) or (2) in the cell cytosol. Bacterial toxins can reach their cytosolic target(s) either upon injection via complex molecular syringes made by the bacterium (secretion systems) or by exploiting internalization inside intracellular acidic compartments. This latter group of toxins will be presented here as they can be used by cell biologists to alter or knock out specific cellular processes in a very specific mode, whilst injected toxins have to be transfected, making the control of their intracellular action somehow problematic.

Exotoxins That Alter Signal Transduction

A large proportion of bacterial toxins appears to have been generated through evolution to avoid host immune

surveillance. A major bacterial strategy to escape immune response is to release protein toxins that alter crucial intracellular signaling pathways. The largest group of bacterial toxins is the PFT, which form pores in the plasma membrane and allow the permeation of a variety of ions, thus interfering with intracellular calcium signaling (Bischofberger *et al.*, 2012). PFTs bind to cell-surface receptors and oligomerize, forming a pore that spans the membrane. In this way, they subvert the osmotic equilibrium of the cell, causing calcium overload and water influx into leukocytes. They may boost cytosolic calcium so much as to cause calcium toxicity. Their application in the study of this major signaling pathway is less useful with respect to pharmacological tools such as calcium ionophores.

Other PFTs such as aerolysin, a toxin produced by the Gram-negative bacterium *Aeromonas hydrophila* and related species, form anion-selective transmembrane channels in host cells; as a consequence, the cell readily loses ions, water, and small molecules (i.e., sugars, amino acids, and nucleic acids) (Fivaz *et al.*, 2001). Loss of K^+ facilitates the formation and activation of the inflammasome, a host inflammatory signaling complex involved in the innate immune response to pathogens via the release of IL-1. Also *Staphylococcus aureus* α -toxin is a PFT that allows the permeation of monovalent ions across the membrane (Menestrina, 1986) and, like aerolysin, activates the inflammasome (Craven *et al.*, 2009). This fundamental intracellular component of the innate immune response is activated by a variety of bacterial toxins acting by various mechanisms, including the TcdB toxin of *Clostridium difficile*, responsible for most cases of nosocomial diarrhea. TcdB cytotoxin inactivates Rho GTPases by glucosylation, thereby affecting cytoskeletal regulation (see below) (Xu *et al.*, 2014).

A large group of protein toxins that deserve special mention are capable of binding to selected microdomains of the cell surface containing sphingomyelin and cholesterol or other

lipids. Their derivatives are very useful to study the structure and dynamics of the plasma membrane as well as the association of specific kinases and other signaling proteins to such microdomains (Skočaj *et al.*, 2013; Abe and Kobayashi, 2014).

Another major intracellular signaling pathway targeted by bacterial toxins is that triggered by the second messenger cyclic adenosine monophosphate (cAMP). The edema factor (EF), produced by *Bacillus anthracis*, combined with the protective antigen (PA) forms the edema toxin (PA + EF). These proteins can be easily produced in recombinant form as separate entities (Dal Molin *et al.*, 2006). PA binds to two different protein receptors which are widely expressed; therefore many different cell types can be affected. PA is activated by specific proteolysis on the cell surface, oligomerizes and binds EF. The PA + EF complex is internalized into endosomes and the acidic pH induces the formation of a mushroom-shaped PA channel that translocates EF into the cytosol (Collier and Young, 2003). Here, EF displays its calmodulin-dependent adenylate cyclase (CyA) activity which persists for many hours, and raises the cytosolic cAMP level with a gradient of concentrations higher around the nucleus and lower below the plasma membrane (Dal Molin *et al.*, 2006; Puhar *et al.*, 2008).

cAMP signaling in host cells is also affected by cholera toxin (CT) from *Vibrio cholerae*, a binary toxin (A–B): the A part is the catalytic subunit and the B part allows cell binding. The B part of CT is a pentamer of identical subunits (AB₅), each one harboring a binding site for the ganglioside GM1 which is present in many cells, including the apical portion of epithelial cells. Fluorescent derivatives of this pentamer are used to map ganglioside microdomains in cells (Conte *et al.*, 2009). CT is internalized inside endosomes, then reaches sequentially the trans-Golgi network (TGN), the Golgi cisternae, finally entering the endoplasmic reticulum (ER) lumen. As several other bacterial protein toxins do (see below), subunit A traverses the ER membrane through the reverse translocon, thereby reaching the cytosol. Subunit A then reaches the CyA complex located on the cytosolic surface of the basolateral membrane, and adenosine diphosphate (ADP)-ribosylates the α subunit of heterotrimeric G proteins of the CyA complex. As a consequence, this enzyme becomes permanently activated, resulting in an increased cAMP level, leading to stimulation of protein kinase A (PKA) and of chloride ion efflux through the cystic fibrosis transmembrane conductance regulator (CFTR) channel. The final result is a large efflux of ions and water across the intestinal epithelium, causing diarrhea (Simon *et al.*, 2014).

Another useful tool for the G heterotrimeric proteins is pertussis toxin (PTX), which is similarly formed by an oligomeric B subunit that binds to oligosaccharide receptors on various eukaryotic cells and by an A catalytic component (Locht *et al.*, 2011). Once internalized, the A protomer is delivered to the ER and from there to the cytosol, where it ADP-ribosylates the α subunit of a G_i protein, leading to a loss of CyA regulation and a rise in cAMP levels. PTX also acts on a number of G_o proteins which are implicated in controlling several intracellular processes (Carbonetti, 2010). *Bordetella pertussis* secretes another virulence factor that interferes with the cAMP signaling of the cell, the CyA. This calmodulin-activated enzyme is capable of crossing the plasma membrane of cells by itself and causes a rapid increase of cAMP below the

plasma membrane (Ladant and Ullmann, 1999; Vojtova *et al.*, 2006; Dal Molin *et al.*, 2006).

The MAPK pathway can also be targeted and inactivated by bacterial toxins. The anthrax lethal factor (LF) toxin combines with PA and enters the cytosol in the same way as EF. Once in the cytosol, LF cleaves the N-terminus of several members of the mitogen-activated protein kinase kinase (MAPKK) family (with the exception of MAPKK5) by virtue of its zinc-dependent metalloprotease activity (Vitale *et al.*, 2000). This results in the inhibition of the MAPK signal transduction pathway, which is key to cellular proliferation and signal transduction processes in the cell (Tonello and Montecucco, 2009). EF and LF synergize in their inhibitory action against immune cells, indicating that the cAMP and the MAPK pathway cross-talk at several points (Baldari *et al.*, 2006).

Photobacterium damsela subsp. *piscicida*, a Gram-negative pathogen responsible for an important fish septicemia, secretes the exotoxin AIP56 (apoptosis-inducing protein of 56 kDa), a major virulence factor. AIP56 is the first known A–B toxin that causes apoptosis by acting on the NF κ B p65 subunit, which is cleaved at a specific site by the metalloprotease subunit A. Other bacterial toxins act similarly, but they are injected via type III secretion systems, and are therefore less simple tools to use in cell biology. On the other hand, AIP56 is specific for fish immune cells (Silva *et al.*, 2013).

The complement system is also a target of bacterial toxins: *Pseudomonas aeruginosa* alkaline protease blocks C3b deposition and complement activation both via the classical and the lectin pathways, thus inhibiting the phagocytosis of the bacterium by human neutrophils (Laarman *et al.*, 2012). The *Neisseria meningitidis* protease NalP cleaves the C3 component of central importance for the activation of both complement pathways (Del Tordello *et al.*, 2014).

Exotoxins That Alter the Cytoskeleton

The cytoskeleton is an essential part of cell architecture and function: it controls cell structure and contacts, cell migration, phagocytosis, signaling, intracellular vesicle trafficking, and other processes. Therefore, it is not surprising that it is among the preferred targets of many virulence factors. Actin is often a direct substrate of ADP-ribosylating toxins. *Clostridium botulinum* C2 toxin, *Clostridium perfringens* iota toxin, *C. difficile* toxin (CDT), *Clostridium spiroforme* toxin (CST) and *Bacillus cereus* vegetative insecticidal protein (VIP), collectively called C2-like toxins, are A–B toxins that ADP-ribosylate actin, leading to its degradation (Simon *et al.*, 2014). Arg-177 of monomeric G-actin is the specific residue that is ADP-ribosylated. As this arginine is at the contact site between actin monomers, this bulky chemical modification prevents actin polymerization. It was observed that the ADP-ribosylation of actin and the consequent decrease of the cortical actin cytoskeleton cause changes in the microtubule system, with formation of microtubule protrusions which extend the cell surface. The superficial network of protrusions seems to enhance adhesion of bacteria and facilitates colonization (Aktories *et al.*, 2012). Intoxication leads to diminished cell–cell contacts and massive edema of intestinal endothelium with increase of fluid secretion.

However, the majority of bacterial toxins affecting the cell cytoskeleton do so indirectly, by interfering with its key

regulators: Rho, Rac, and Cdc42. By switching between a guanosine diphosphate (GDP)-bound inactive and a guanosine triphosphate (GTP)-bound active state, a transition controlled by activating (guanine nucleotide exchange factor (GEF) proteins) and deactivating (GTPase-activating proteins (GAP) proteins) components, these small GTPases control actin dynamics. The activity of these proteins can be modified by bacterial toxins via specific ADP-ribosylation, glycosylation, or deamidation, producing different cellular outcomes (Aktories, 2011).

Recently, the use of a variant of *C. difficile* toxin B (TcdB), a large (~270 kDa) glucosyltransferase that targets the Ras superfamily of small GTPases causing its irreversible glycosylation, has helped to elucidate the role of the Rho GTPases in the control of centrosome recruitment and the activation of the mitotic kinases. Treatment of synchronized hela cells with TcdB in the G2 phase prevented the centrosomal activation of PAK, Aurora A, and Cdk1, and delayed mitotic entry (May *et al.*, 2014).

Insect pathogens can produce toxin complexes that target the cytoskeleton of insect cells. Such tripartite complexes, known as Tc or ABC toxins, are produced, among others, by entomopathogenic *Photobacterium luminescens*, which lives in symbiosis with nematodes. These nematodes invade insect larvae and release the bacteria in the intestine, causing the death of insects by the action of toxin complexes. Tc toxin consists of TcA, TcB, and TcC components: TcA is the binding and membrane translocation component, and TcB is a functional linker between TcC and TcA, and is also involved in the translocation of the toxin. TccC3 ADP-ribosylates actin at threonine 148, resulting in actin polymerization, whereas TccC5 modifies Rho proteins at glutamine 61/63, inducing their activation. The concerted action of both toxins inhibits phagocytosis of target insect cells and induces extensive intracellular polymerization and clustering of actin. Since Tc toxin targets insect cells, it could be exploited in studies that employ *Drosophila melanogaster* as model system. Several human pathogenic bacteria produce related toxins (Lang *et al.*, 2010; Simon *et al.*, 2014).

In the nervous system, the Rho GTPases play a key role in several processes, controlling neurotransmitter release, the morphogenesis of dendritic spines, and synaptic plasticity; mutations in proteins involved in Rho GTPase signaling may be causative of some forms of intellectual disabilities. Rho GTPases can be blocked in their activated, GTP-bound state by a bacterial protein toxin from *Escherichia coli* named cytotoxic necrotizing factor 1 (CNF1). CNF1 catalyzes the deamidation of a single glutamine residue of the Rho molecules, thus inhibiting GTP hydrolysis and leading to their persistent activation. CNF1 is able to increase brain plasticity in adulthood (Ceri *et al.*, 2011). The ability of CNF1 to act on synaptic plasticity by modulating Rho GTPases activity may be exploited to promote brain repair (Travaglione *et al.*, 2014), but its action is not limited to neurons, and CNF1 is very useful for the study of the role of Rho in different cellular processes and in cancer growth (Vannini *et al.*, 2014).

In addition to C2 toxin and BoNT/C and BoNT/D neurotoxins, type C and D strains of *C. botulinum* produce a Rho-modifying ADP-ribosyltransferase named C3 toxin. C3 transferases are not restricted to Clostridia, but are released by many different bacterial species. C3 toxins modify an asparagine

residue of RhoA, B, and C, at variance from many bacterial ADP-ribosyltransferases that usually target arginines or cysteines, and have been widely used to dissect the cellular functions of Rho GTPases (Vogelsgesang *et al.*, 2007). Their cellular uptake mechanism has not been clarified yet, since they lack a transporter B subunit. Several mechanisms of entry into host cells have been proposed so far: (1) unspecific internalization, (2) internalization mediated by pore-forming cytotoxins produced by the same bacteria, and (3) internalization of the bacterium that, once inside the host cell, can secrete the toxin directly into the host cytosol. Due to their poor cell accessibility C3 toxins must be transfected, microinjected, or fused with the binding and translocation subunit of other toxins to be delivered into cells (Vogelsgesang *et al.*, 2007).

Exotoxins That Interfere with Intracellular Trafficking

The various organelles of eukaryotic cells are interconnected by a continuous and active trafficking of vesicles, which allows for the exchange, uptake, and delivery of molecules. Vesicle trafficking is governed by several proteins, among which the three SNARE (SNAP (Soluble NSF Attachment Protein) Receptor) proteins VAMP, SNAP-25, and syntaxin play a major role, together with members of the Rab family of small GTPases. There are many different isoforms of SNAREs and Rabs, which are involved in different events of vesicle traffic (Lang and Jahn, 2008). Several human bacterial pathogens (*Legionella pneumophila*, *Listeria monocytogenes*, *Salmonella enterica*, etc.) create specialized niches in macrophages and epithelia by altering Rab GTPase functions. This strategy allows them to escape degradation and obtain nutrients essential for growth and survival (Stein *et al.*, 2012).

Tetanus neurotoxin and botulinum neurotoxins (whose number is rapidly growing) cleave some isoforms of SNAREs at single peptide bonds (Rossetto *et al.*, 2014). However, they only enter neurons that express both their polysialoganglioside and protein receptors and their capability of cleaving the specific SNARE isoform under study has to be controlled before use. Cleavage by a botulinum neurotoxin of a particular SNARE isoform of a given animal species depends on the sequence of the cleavage site as well as on the sequence of several exosites which are located at a distance from the cleavage site (Pantano and Montecucco, 2014). Thus, botulinum neurotoxins are very useful in studying the role of neurotransmitters or other biological molecules released by fusion of intracellular vesicles with the plasma membrane and in intercellular signaling, because they provide a cheap knockout of the process mediated by a given SNARE protein.

Tetanus neurotoxin, together with the pentameric binding protomer of cholera toxin, are the two best characterized markers of retroaxonal transport inside motoneurons from the periphery to the spinal cord (Bercsenyi *et al.*, 2013). In addition, one can use bacterial toxins to trace vesicular transport inside cells. For example, Shiga toxin (STx) from *Shigella dysenteriae*, cholera toxin, and *P. aeruginosa* exotoxin A (ExoA) bind to their cell receptors via the B subunits, and are then endocytosed inside early endosomes which undergo progressive lumen acidification. Instead of being directed to late endosomes and then to lysosomes for degradation, these toxins transit to the TGN and from there to the ER. Once in the ER, they exploit a cellular

mechanism devoted to the degradation of newly synthesized misfolded proteins, called endoplasmic reticulum-associated protein degradation (ERAD). Usually misfolded proteins are driven through a reverse translocon pore to be discarded into the cytosol where they become substrates for ubiquitination and are degraded inside the proteasome (Johannes and Wunder, 2011). These bacterial toxins are ubiquitinated poorly or not at all in the cytosol; they therefore escape such degradation route and can exert their enzymatic activities within the host cell.

Exotoxins That Block Protein Synthesis or Protein Folding

Many bacterial toxins block protein synthesis and/or folding, with deleterious consequences particularly in organs that strictly rely on protein synthesis for their function. The most studied member of this family is diphtheria toxin (DT), which represents the paradigm of the bacterial toxins made of two parts (A for active and B for binding), held together by a single interchain disulfide bond. DT is endocytosed by most cells and when exposed to the acid pH of the endosomal lumen it penetrates the membrane, causing translocation of the A protomer into the cytosol. DT-A is an ADP-ribosyl-transferase which specifically transfers the ADP-ribose from NAD⁺ to the elongation factor 2 (EF-2), thereby causing a complete inhibition of protein synthesis and cell death (Collier, 2001). It was actually demonstrated that a single molecule of the enzymatically active fragment A of DT is by itself able to kill an eukaryotic cell (Yamaizumi *et al.*, 1978). Other bacterial toxins that block protein synthesis are ExoA, which acts in the same way as DT, as well as STx and Shiga-like toxins from some enterohemorrhagic strains of *E. coli*. STx is an AB₅ exotoxin which binds to glycolipids of the cell surface via the B5 protomer, and is endocytosed; the A subunit is then delivered to the cytosol, where it displays N-glycosidase activity specific for a single adenine of ribosomal RNA, thus blocking protein synthesis. These toxins, as well as the plant toxin ricin, could be used to study the kinetics of protein synthesis.

Cell life is dependent on the correct folding of proteins to be exported, an event that takes place in the ER. A central player in this process is the chaperone Binding Immunoglobulin Protein (BiP). BiP is cleaved by a bacterial toxin produced by *E. coli* associated to an uremic syndrome, leading to inactivation of protein folding (Paton *et al.*, 2006; Montecucco and Molinari, 2006).

Exotoxins That Alter Deoxyribonucleic Acid (DNA)

The cytolethal distending toxins (CDTs) are bacterial genotoxins that cause DNA damage in the target cells. They are produced by a variety of Gram-negative pathogenic bacteria, among them *E. coli*, *Shigella dysenteriae*, *Campylobacter sp.*, *Helicobacter sp.*, and *S. enterica*. The mechanism of cytotoxicity of CDTs is unique: they enter into eukaryotic cells, reach the nucleus, and break double-stranded DNA, resulting in the arrest of the cell cycle and, eventually, in the activation of the apoptotic program of cell death. CDT is the product of an operon encoding three proteins: CdtA, CdtB, and CdtC. The catalytic subunit CdtB has deoxyribonuclease I (DNase I)-like activity, whereas CdtA and CdtC are binding proteins for delivering CdtB into target cells. All three subunits are essential to confer full activity to the

holotoxin. Binding of CDT depends on the presence of intact lipid rafts, and the toxin is internalized via dynamin-dependent endocytosis into early and late endosomes. The CdtB subunit further transits to the Golgi complex, and is then retrogradely transported to the ER. Translocation from the ER does not require the ERAD pathway, and protein unfolding. How the nuclear translocation of the CdtB subunit takes place is still an open question. In response to DNA damage, cells activate a series of complex mechanisms that aim at repairing the genome and limiting the probability of lethal or permanent genetic damage (Guerra *et al.*, 2011). Recently, a novel toxin consisting of a B binding protomer and of two catalytic A subunits has been isolated from *S. enterica*. One A subunit is similar to PTX, whilst the other is a DNase (Song *et al.*, 2013).

Final Considerations

The field of bacterial toxins acting upon host cells is continuously expanding, thanks to the use of genomic, transcriptomic, and proteomic methods, which are revealing the large variety of tools that bacteria have devised in their continuous struggle to increase their presence in the world. In addition, the same evolutionary processes have taken place in the animal and plant kingdoms, and other toxins not considered here may be found useful in cell biology studies.

The Gut Microbiome

The emerging field of microbiome research refers to the collection of microorganisms found within human, animal, or plant hosts, and their genetic information. Amazingly, the number of microbial cells found within the human body is approximately 10 times greater than the sum of all human somatic and germ cells. Accordingly, the microbial genetic information within our bodies is 150 times greater than our own. Our microbial partners can be found throughout the body, including the gastrointestinal tract, skin, nose, mouth, and urogenital system, with different typical compositions in different organs (Human Microbiome Project, C., 2012). The human microbiome is composed of bacteria, archaea, viruses, and fungi. For the purpose of this article, we will refer mainly to the bacterial component of the microbiome, as this has been the most extensively studied. The largest bacterial community in our body resides in the gastrointestinal tract. In the colon, for example, bacterial densities can reach up to 10^{11} cells/g luminal contents (Simon and Gorbach, 1984). Together, gut microbes form a community referred to as the microbiota. The human gut microbiota is made up of more than 1000 different microbial species (Human Microbiome Project, C., 2012). Most of these microbes are anaerobic and cannot be grown using routine laboratory procedures. Our gut microbiota has been shown to have broad effects on our health and well-being, impacting our immune system and metabolism, detoxifying various ingested components, and performing other functions. Thus, the majority of gut microbes are generally viewed as beneficial symbionts, having reciprocal interactions with their hosts. Changes in gut microbiota composition are correlated with a wide range of disease states.

The human microbiome is highly variable both within a single subject over time and different environmental conditions, and between different individuals. While the microbiome is greatly affected by environmental factors, the genetic contribution of the host seems to be polygenic and mild, as there can be large differences in microbial populations between identical twins (Turnbaugh *et al.*, 2009b).

Microbiome Research Methodology (Approaches and Tools)

Microbiome research aims to decipher which are the components that constitute the overall microbial populations, how they interact and affect one another, how they are affected by the host environment, and how they affect the host at various levels.

The ability to thoroughly characterize microbiota components came only with the development of next-generation sequencing (NGS) techniques, including Roche 454, ion torrent and Illumina, as many of the microbes in the human body are not readily cultured. Even with culture under

anaerobic conditions to enlarge the number of potentially culturable microbes, only about 50% of the microbial populations are represented (Goodman *et al.*, 2011). NGS also enables high-throughput experiments, sequencing millions of reads simultaneously and analyzing them with bioinformatic methods.

16S rRNA Gene Surveys

The most commonly used method to date for characterizing bacterial communities is sequencing of the 16S rRNA bacterial gene. While the 16S rRNA gene includes highly conserved regions, it also includes highly variable regions, enabling the distinction between thousands of bacterial sequences, representing different microbial species. These 16S surveys can be used to answer the question: 'What are the microbial components in the sample?' The sequences from a sample can be assigned taxonomy using databases of known 16S gene sequences. The number of sequences in a sample that are classified as a specific microbe can give an estimate of the relative abundance of that microbe within the sample. Microbial diversity can also be calculated both within a single sample (alpha-diversity), and between different samples (beta-diversity).

Metagenomics (Whole-Genome Shotgun Sequencing)

Another way to characterize the microbiome is with whole-genome sequencing (shotgun sequencing). In this technique all genetic material in the sample is sequenced together, and only later segregated as host versus microbial. This approach offers information regarding the bacterial genes present, thereby hinting at the roles and abilities of the microbial populations. Such functional metagenomic data answers the question: 'What could the microbial components potentially do?'

Metatranscriptomics

Additionally, reverse-transcribed RNA sequencing from a sample can reveal metatranscriptomic data, highlighting the microbial genes actually expressed, thereby answering the question: 'What are these microbes really doing?'

Metabolomics

Metabolic profiling, usually by chromatography and spectrometry, reveals the composition of small-molecule metabolites from both host and microbial metabolism in a sample. By combining these data with the genetic sequences of a sample, it is possible to find correlations between levels of specific metabolites and microbial populations (Ursell *et al.*, 2014). This approach can answer the question: 'How do these microbes affect host metabolites?'

Germ-Free Animals

Germ-free (GF) organisms, grown under sterile conditions, are a useful tool for understanding the roles of the microbiome. Observations of GF animals have revealed alterations in immune system components, hormonal levels, metabolism, and even behavior. GF models allow the introduction of specific bacteria, creating a gnotobiotic model, and studying their effects on the host. Microbiota transplants, in which fecal bacteria from a donor are transferred into a GF mouse, can also assess the effects of the microbiome. Such experiments have shown that exposure to different types of bacterial compositions can lead to a variety of health outcomes, proving a causal relationship between microbiota and health states. Another method used to alter microbiome composition in rodents is cohousing of animals with different microbial compositions.

Constituents of the Microbiome

Bacteria

The bacterial components of the microbiome are the most dominant and extensively studied to date. The two predominant bacterial phyla represented in the gut microbiome are Firmicutes and Bacteroidetes. Additional phyla include Actinobacteria, Proteobacteria, Verrucomicrobia, Fusobacteria, and Cyanobacteria (Eckburg *et al.*, 2005).

Archaea

The archaeal gut community is composed mainly of methanogens. While methanogens are not found in all fecal samples, the dominant methanogen in the human gut is *Methanobrevibacter smithii*. Methanogen abundance is higher following a high-carbohydrate diet, and in obese individuals. In fact, methanogens may be a risk factor for obesity, since in the process of producing methane they oxidize hydrogen and complete fermentation of carbohydrate substrates, leading to higher production of short-chain fatty acids (Conway de Macario and Macario, 2009; Hoffmann *et al.*, 2013). Methanogens may also play an immunological role, capable of inducing an inflammatory cytokine response (Bang *et al.*, 2014). Interestingly, their abundance is higher in inflammatory bowel diseases (IBD) patients, who also display an antigen-specific IgG response to the methanogens (Blais Lecours *et al.*, 2014).

Viruses

The human virome is unique to each individual and includes many viruses, including previously uncharacterized bacteriophages, which may play a defensive role against pathogens (Minot *et al.*, 2013). As part of the Human Microbiome Project (HMP), the dsDNA viruses of 102 individuals were analyzed, and on average included 5.5 viral genera per individual. These viruses included herpesviruses, papillomaviruses, polyomaviruses, adenoviruses, anelloviruses, parvoviruses, and circoviruses. Most of these viruses were stable over time (Wylie *et al.*, 2014). Nonetheless, due to their rapid evolution, horizontal gene transfers, and intimate interactions with host

nucleic acids, we are only beginning to decipher the human viral communities on a large scale (Abeles and Pride, 2014).

Eukaryotes

Our bodies are colonized with populations of fungi, also termed the mycobiome, as well as several protists. There are at least 66 genera of fungi found in the gut microbiome (Hoffmann *et al.*, 2013). Similarly to the other components of the microbiome, the fungal components are likely to impact host health and disease (Gouba *et al.*, 2014). Fungi have important roles interacting with innate immune cells, via receptors such as Dectin-1 (Underhill and Iliev, 2014). It has been found that disruption of the Dectin-1 receptor function can lead to colitis, perhaps due to loss of interactions with host fungi (Iliev *et al.*, 2012). Additionally, there have been studies on other eukaryotic members of the gut microbiome such as the single-celled protozoa, *Blastocystis*, which was present in over 50% of adult samples studied (Scanlan *et al.*, 2014).

The Roles of the Microbiome

The most obvious role of the gut microbiome is in food digestion, performing numerous biochemical reactions including breaking down starch, producing amines and phenols from proteins, and metabolizing xenobiotics into multiple metabolites. The commensal microbiota can also produce vitamins.

In addition, the gut microbiota affects the host immune system. Beyond influencing the gut barrier function and repressing pathogenic microbes, the gut microbiota plays a role in modulating the host immune response, both locally and systemically (Kamada *et al.*, 2013). In the absence of commensal bacteria, GF mice have impaired development of the innate and adaptive immune system (Hill and Artis, 2010; Honda and Littman, 2012; Hooper *et al.*, 2012; Littman and Pamer, 2011), reduced numbers of IgA-producing plasma cells (Crabbe *et al.*, 1969), impaired development of gut-associated lymphoid tissues (Kelly and Mulder, 2012) and a decreased percentage of CD4⁺ T cells (Ostman *et al.*, 2006). Additionally, T helper 17 (TH17) cells, which produce pro-inflammatory cytokines, are regulated by gut bacteria and are promoted specifically by segmented filamentous bacteria (Tanabe, 2013). Finally, autoimmune diseases have also been correlated with alterations of the microbiome (dysbiosis).

Another effect that the microbiota has on their hosts includes altering hormone levels. There have been numerous reports of microbiota both producing and regulating host hormones such as serotonin, epinephrine, norepinephrine, dopamine, etc. These, in turn, affect host behavior, metabolism, and immunity.

The effects of the microbiome on host brain functions and behavior are particularly interesting. Microbiota in mice has been shown to affect depression, anxiety, and exploratory behavior. GF mice display a variety of behavioral alterations compared to specific pathogen-free (SPF) mice, including changes in cognitive function, memory, stress response,

anxiety, and social behavior (Diaz Heijtz *et al.*, 2011; Gareau *et al.*, 2011; Neufeld *et al.*, 2011). These behavioral alterations are concurrent with alterations found in serotonin levels and lower levels of brain-derived neurotrophic factor, in GF vs. SPF mice (Bercik *et al.*, 2011; Grenham *et al.*, 2011). In a different study, *Lactobacillus* was found to regulate emotion and behavior, as well as central GABA receptor expression, via the vagus nerve (Bravo *et al.*, 2011). In *Drosophila melanogaster*, it was shown that microbial symbionts drive sexual preference, and that these change upon use of antibiotics or addition of specific bacteria (Sharon *et al.*, 2010). Although much remains to be learned, there are clues that bacteria may affect behavior in humans, as well. Minocycline, an antibiotic with a broad-spectrum activity, has been recently suggested as a candidate treatment for depression and schizophrenia (Jhamani *et al.*, 2013; Soczynska *et al.*, 2012). Furthermore, digestive diseases such as IBD have been reported to lead to depression and anxiety (Walker *et al.*, 2008), although precise mechanisms have not yet been described. Additionally, in a human study testing effects of probiotics on brain function, results showed altered brain activity in regions associated with central processing of emotion and sensation (Tillisch *et al.*, 2013). Thus, while further research is needed to understand precise relationships, mechanisms and interactions, there are significant clues for broad microbial effects on their hosts.

Changes in the Gut Microbiome Throughout Life

Shifts in the composition of the microbiome occur naturally at different stages in life, such as infancy, childhood, puberty, old age, pregnancy, and others (Spor *et al.*, 2011). Below, we describe the typical microbiome composition for the different age groups (also described in Figure 1).

Pregnancy

During pregnancy, there is an increase of Proteobacteria and Actinobacteria, and less richness (number of different types of microbial species) is observed. These changes correlate with increased weight gain, hormonal and immunological changes, and insulin desensitization. Interestingly, when GF mice receive fecal transplants from third trimester pregnant women, they develop induced adiposity and insulin desensitization, compared with mice receiving fecal transplants from women in their first trimester. This suggests that the bacterial populations may play a role in these metabolic processes. These aberrant microbiotas are then passed to the neonates at birth (Koren *et al.*, 2012).

Birth and Infancy

While it has long been assumed that we are born sterile, new evidence suggests that the placenta harbors bacteria (Aagaard

Figure 1 Changes in gut microbiota composition throughout life. Distinct age-related alterations in microbial composition as seen by the colored bars representing typical distribution of the major bacterial phyla following 16S analysis (upper part of figure, adapted from Ottman, N., *et al.*, 2012). The function of our microbiota: Who is out there and what do they do? *Frontiers in Cellular and Infection Microbiology* 2, 104), and by microbial stability (relative compositional changes throughout time) (bottom part of figure, adapted from Spor, A., Koren, O., Ley, R., 2011). Unraveling the effects of the environment and host genotype on the gut microbiome. *Nature Reviews. Microbiology* 9 (4), 279–290.

et al., 2014). A newborn's microbiome is greatly affected by the maternal microbiome (Spor *et al.*, 2011) and by the mode of delivery, so that babies born by vaginal birth obtain an initial microbial inoculum that resembles their mother's vaginal microbiome, as opposed to the microbiome of babies born by cesarean section, which is more similar to their mother's skin microbiota (Spor *et al.*, 2011). The microbiome composition changes dramatically during the first 2–3 years of life (Spor *et al.*, 2011), and then stabilizes. The infant's microbiota is characterized by less diversity compared to that of an adult, harboring a high abundance of bacteria that function in lactate utilization. Transition to solid foods has been shown to increase the abundance of Bacteroidetes as well as bacteria that utilize carbohydrates, and are involved in vitamin biosynthesis and xenobiotic degradation (Koenig *et al.*, 2011). It has been further shown that the gestational age greatly affects the development of the gut microbiota, so that premature infants take longer to assemble bacterial communities (La Rosa *et al.*, 2014).

Adulthood

The largest microbiome studies to date that describe the human adult microbiome have been performed by consortiums named the Metagenomics for the Human Intestinal Tract (MetaHIT), and the HMP. MetaHIT was the first to perform metagenomics on fecal samples from 124 human subjects, and found that the gut microbiota includes ~1000 species. Interestingly, they found great diversity of microbial species between subjects, so that only 18 core species were found in all subjects. However, when analyzing the metagenomic data, they found much greater similarity, suggesting that while the precise microbial species may differ between subjects, their genes and functions may be the same (Qin *et al.*, 2010). The HMP was initiated by the US National Institutes of Health in an attempt to identify and characterize the microorganisms found in association with health and disease in humans. So far, the first phase of the project characterized the composition and diversity of microbial communities inhabiting a variety of body sites, and evaluated the genetic metabolic potential of these communities. All together, almost 5000 samples were collected and sequenced from 242 healthy volunteers, representing 15 (in males) to 18 (in females) body sites, including nasal passages, oral cavities, skin, gastrointestinal tract, and the urogenital tract. Their reference database is the largest one available to date. It appears that the microbial populations at different body sites are unique, and that there is higher diversity between body sites rather than between different subjects. Even throughout the gastrointestinal tract there are significant population variations according to location. This may not be surprising as the microenvironments are different at various locations, including variations in pH levels. The current phase of studies by the HMP focuses on microbiome-associated diseases (Human Microbiome Project, C., 2012).

Aging

In the elderly, the microbiota once again becomes less stable (Spor *et al.*, 2011), and is dominated by members of Bacteroidetes. In a study comparing the gut microbiota

composition of 161 elders (over age 65) and 9 younger controls, a greater proportion of *Bacteroides* were found in the elders as well as distinct abundance patterns of *Clostridium* groups (Claesson *et al.*, 2011). These alterations may be due to changes in diet, a more sedentary lifestyle, frailty, background diseases, and/or states of inflammation (Candela *et al.*, 2014). On a functional level, there are over 100 bacterial genes correlated with host aging. The microbiome in the elderly is characterized by loss of SCFA-producing genes and an overall decrease in the saccharolytic potential, while proteolytic functions are more abundant than in younger adults. Additionally, in samples from the elderly, there were more opportunistic pro-inflammatory bacteria (Rampelli *et al.*, 2013). In a study that compared the microbiota of elders living in the community versus microbiota of elders in long-stay care, the latter was significantly less diverse and correlated with frailty (Claesson *et al.*, 2012).

Factors Influencing the Microbiome

Changes in environmental factors such as diet, geographic location, and use of antibiotics, which may occur throughout life, are associated with changes in the gut microbial communities.

Diet and Geographic Location

The factor that most strongly influences the composition of the microbiome appears to be diet. The effects of a dietary change on the microbiota composition can be extremely rapid. In a study of short-term dietary change (5 days long) in which subjects received an animal-based diet, there were observed changes in microbial communities compared to baseline after as little as 2 days, including changes in microbial gene expression (David *et al.*, 2014b). Certain dietary compositions have been associated with higher abundance of a specific genus, such as significant *Bacteroides* in a protein-rich animal fat diet and significant *Prevotella* in a carbohydrate-rich diet (Wu *et al.*, 2011).

In a unique study in which the gut microbiota of two subjects was followed daily over the course of two years, it was possible to examine the overall stability of the microbial components. Among the short-term alterations, changes in fiber intake correlated with abundance changes among 15% of gut microbiota members within 1 day. Additionally, travel to the developing world had a significant effect on the microbial diversity of one of the subjects by nearly doubling the Bacteroidetes to Firmicutes ratio, which reverted upon return (David *et al.*, 2014a).

Several studies showed significant differences in gut microbiota between populations from around the world, mostly due to dietary diversity. In a large study comparing the microbiome of 531 individuals from Venezuela, rural Malawi and US metropolitan areas, there were distinct differences between groups. These differences were most likely affected by the different diets; while a typical US diet is rich in protein, the diets in Malawi and Venezuela are dominated by corn and cassava. Thus, the US samples appeared to more strongly differ from the two other groups (Yatsunenko *et al.*, 2012). In another study, large

differences in microbial populations were found between children from the rural village of Boulpon in Burkina Faso (BF) and European children (De Filippo *et al.*, 2010). While the African children's diet was high in fiber and polysaccharides, the European children followed a modern western diet. Accordingly, the African (BF) children showed significantly higher levels of Bacteroidetes and lower levels of Firmicutes, while the European children presented an opposite profile with high Firmicutes and low Bacteroidetes (see Figure 2). Additionally, the African children exhibited unique bacteria from the genus *Prevotella* and *Xylanibacter*, which contain bacterial genes enabling digestion of cellulose and xylan hydrolysis. On the other hand, *Enterobacteriaceae* levels (*Shigella* and *Escherichia*) were significantly higher in the European children. In a study of the Hadza, a community of Tanzanian hunter-gatherers, unique microbial components were observed that were consistent with their foraging lifestyle and differences in activity levels between sexes. In addition to higher levels of microbial richness and biodiversity compared to Italian urban controls, they did not harbor any *Bifidobacterium* and they exhibited differences in microbial composition between sexes. Furthermore, enrichment in *Prevotella*, *Treponema*, and unclassified *Bacteroidetes*, as well as a peculiar arrangement of *Clostridiales* taxa were observed, which may enhance the Hadza's ability to digest fibrous plant foods (Schnorr *et al.*, 2014).

Exercise

Exercise has been shown to increase bacterial diversity in humans. In a study comparing the gut microbial composition of rugby athletes to healthy male controls, the number of phyla, families and genera were all doubled in the athletes (Clarke *et al.*, 2014). Changes in microbial composition due to exercise have also been shown in a rat model in which exercised rats had a different microbiota leading to greater levels of n-butyrate compared to sedentary rats (Matsumoto *et al.*, 2008). Two additional rodent studies have shown a higher abundance of *Lactobacillus* following exercise (Choi *et al.*, 2013; Petriz *et al.*, 2014).

Antibiotics

As expected, use of antibiotics affects not only the targeted pathogen, but also the overall microbial composition. While most of these changes are short-term, and recovery to baseline microbial composition occurs within a few days or weeks, long-term effects have also been reported. The typical short-term alterations of the microbiota due to antibiotics include decreased taxonomic richness, evenness, and diversity, but the precise effects vary between patients (Dethlefsen *et al.*, 2008). One study reported that a week-long treatment of clarithromycin and metronidazole led to an immediate decrease in Actinobacteria abundance (Jakobsson *et al.*, 2010). Another study showed that levels of Firmicutes were most affected after treatment with eight different types of antibiotics (Maurice *et al.*, 2013). However, long-term effects of antibiotics on the microbiome including depletion of certain taxa and altered microbial communities have been shown to last more than six months, and even up to four years after short-term exposure (Jakobsson *et al.*, 2010). The effects of antibiotics on the

Figure 2 16S rRNA gene surveys reveal a clear separation of two populations of infants. (a and b) Pie charts of median values of bacterial genera present in fecal samples of rural Burkina Faso (a) versus European children (b), as identified by RDP classifier v. 2.1. Rings represent corresponding phyla (Bacteroidetes in green and Firmicutes in red) for each of the most frequently represented genera. (Adapted from De Filippo, C., *et al.*, 2010. Impact of diet in shaping gut microbiota revealed by a comparative study in children from Europe and rural Africa. *Proceedings of the National Academy of Sciences of the United States of America* 107 (33), 14691–14696).

microbiome can be especially crucial in infancy. In a mice study in which low-dose penicillin (LDP) was delivered from birth, perturbations in microbial communities were observed, as well as sustained alterations in host metabolism and adiposity. Transplantations of the microbiota resulting from LDP to germ-free mice proved that the microbiota had a causative effect on changes in metabolism and adiposity (Cox *et al.*,

2014). Furthermore, as one of the roles of the healthy microbiota is to enhance resistance to microbial pathogens, long-term use of antibiotics can weaken this defense mechanism, leading to susceptibility and subsequent disease (Keeney *et al.*, 2014). In conclusion, antibiotics have a significant effect on microbiota composition, a factor that should be taken into clinical consideration.

The Microbiome and Disease

Changes in the composition of the microbiome (dysbiosis) are associated with a growing list of diseases, including obesity, IBD, diabetes, metabolic syndrome, and others ((Spor *et al.*, 2011); see Figure 3). Such associations raise the question of whether the dysbiosis contributes to, or is a result of the disease. Microbiome transplant experiments have demonstrated a role of the microbiome in several diseases: several phenotypes could be transferred via the microbiota, such as enhanced fat gain (Ridaura *et al.*, 2013; Turnbaugh *et al.*, 2009a), metabolic syndrome (Vijay-Kumar *et al.*, 2010), colitis (Garrett *et al.*, 2007) and increased insulin sensitivity (Vrieze *et al.*, 2012). There have also been reports of successful fecal transplantation from healthy individuals to treat IBD patients (Bennet and Brinkman, 1989; Borody *et al.*, 2003). Together, these transplantation-based studies imply that the specific composition of the microbiota can be an important factor in the onset, and possibly the progression of chronic diseases.

Microbiota have also been implicated in a growing number of additional disease states including: autoimmune diseases, autism, cancer, *Clostridium difficile* infection (CDI), and necrotizing enterocolitis (NEC).

C. difficile Infection

This condition includes *C. difficile* overgrowth in the digestive tract, which can cause mucosal inflammation and damage, leading to colitis. The cause in many cases is prolonged use of broad-spectrum antibiotics which lead to dysbiosis and elimination of many microbial components, while enabling *C. difficile* overgrowth. Fecal microbial transplants have proven to be effective for treatment of severe CDI (Koenigsnecht and Young, 2013). While CDI is associated with reduced microbial diversity and richness, these are regained following fecal transplants (Shahinas *et al.*, 2012). Furthermore, while the microbial populations in CDI are dominated by Proteobacteria and Bacilli, following treatment, there are more species from the Bacteroidetes and Firmicutes phyla, including butyrate-producing bacteria (Fuentes *et al.*, 2014). Potentially, a combination of stable probiotics may lead to efficient treatment of CDI, and is therefore a major goal.

Obesity

The obesity-related changes to the microbiota are probably the most extensively studied so far. Changes in the abundances of bacterial phyla were first linked to obesity in mice. It was observed that the microbiota of obese mice was less diverse and that the ratio of Firmicutes to Bacteroidetes increased as

Figure 3 Dysbiosis in disease states. The gut microbial composition changes throughout various disease states, with typical bacterial phyla becoming overrepresented (up arrows), or under represented (down arrows) compared to the healthy control distribution. mice became fatter (Ley *et al.*, 2005). This change was also observed in 12 humans who were on a 52-week weight-loss diet; as the subjects lost weight, the ratio of Firmicutes to Bacteroidetes decreased (Ley *et al.*, 2006). A different study tested energy extraction as an attribute of microbiota composition and weight. It was found that the more overweight people were, the more efficiently their microbiota extracted energy from the same amount of food (Turnbaugh *et al.*, 2006). Controversially, there have been other studies that exhibit different results. For example, a few human studies described a greater Bacteroidetes abundance in overweight (Schwiertz *et al.*, 2010) or a greater Firmicutes abundance in lean people (Zhang *et al.*, 2009). Other studies did not observe any changes at the phylum level of Firmicutes and Bacteroidetes (Armougom *et al.*, 2009), or found changes in different phyla such as Actinobacteria (Turnbaugh *et al.*, 2009a). Some

of the recent human studies investigated changes at other taxonomic levels, e.g. family, genus and species etc. (Ley *et al.*, 2005). Despite these different observations, the consensus is that the microbiota composition changes in obesity, and that these changes are associated with inflammation, insulin resistance and adiposity (Ley *et al.*, 2005). Microbiota transplantation studies in GF mice have shown that transplantation of microbiota from obese individuals results in mice with increased body mass and adiposity. These effects can be reversed when mice are co-housed with mice receiving microbiota transplants from lean individuals, or when mice receive a diet characterized by low levels of saturated fats and high consumption of fruits and vegetables (Ridaura *et al.*, 2013).

Bariatric Surgery

Another direction for studying the role of bacteria in obesity is by looking at the microbial effects of a Roux-en-Y-gastric bypass (RYGB), a treatment for obesity, which results in rapid weight loss. Several studies have looked at the effects of bariatric surgery on the diversity of the microbiota in human, rat and mouse fecal samples, and reported fairly congruent trends (Zhang *et al.*, 2009; Furet *et al.*, 2010; Li *et al.*, 2011; Liou *et al.*, 2013). A 16S rRNA microbial composition survey (Zhang *et al.*, 2009) reported decreased levels of Firmicutes and a proportional increase in the γ -Proteobacteria in patients who underwent surgery compared to normal-weight and obese humans. A different study using a quantitative PCR approach to quantify levels of specific groups of bacteria in fecal samples derived from humans before and after RYGB, reported an increase in the *Bacteroides/Prevotella* group and *Escherichia coli* three months after surgery and a decrease in the abundance of Bifidobacteria as well as subtypes of Firmicutes, notably the *Lactobacillus/Leuconostoc/Pediococcus* group (Furet *et al.*, 2010). A study looking at the effect of RYGB on the fecal microbiota of non-obese rats also reported a decrease in the abundance of Firmicutes and a substantial increase in the abundance of Proteobacteria, especially of *Enterobacter hormaechei* (Li *et al.*, 2011). An additional study investigating the effect of RYGB in mice reported that there was an increase in Proteobacteria and Verrucomicrobia (Liou *et al.*, 2013). This study also reported that transferring the microbiota from operated mice to GF mice resulted in weight loss and decreased fat mass in the GF mice. This study demonstrates that the microbiota plays an active role in the success of the surgery.

Metabolic Syndrome

Metabolic syndrome describes a group of disorders that when concurrent, increase the risk for type 2 diabetes and cardiovascular disease. These disorders also include excess weight; however, unlike obesity in which the microbiota is suggested to extract energy more efficiently, in metabolic syndrome the hypothesized mechanism is different. Mice with metabolic syndrome have higher levels of Proteobacteria and lower diversity than their healthy counterparts. Recently it was shown that changes in the microbiota composition correlated with metabolic changes and that the metabolic syndrome phenotype could be transferred to GF mice simply through transfer of the

microbiota (Vijay-Kumar *et al.*, 2010). The mechanism proposed for the involvement of the microbiota is their induction of low-grade inflammatory signaling, which in turn, could lead to metabolic syndrome (Vijay-Kumar *et al.*, 2010).

Malnutrition

Since diet plays an important factor in shaping the microbiota composition, it is not surprising that malnutrition affects the microbiota. In a study of Bangladeshi children with severe acute malnutrition (SAM) it was found that their microbiota composition was distinct from healthy children, and only partially changed after receiving caloric replenishment (Subramanian *et al.*, 2014). Comparing both healthy and SAM children at different ages enabled definition of the normal microbial composition by age, and indicated that the SAM children retained an immature microbial composition, even after nutritional treatment.

IBD (Ulcerative Colitis, Crohn's Disease)

Ulcerative colitis (UC) and Crohn's disease (CD) are commonly known as IBD. The microbiota of IBD patients has been found to differ from the microbiota of healthy subjects, including a decrease in diversity and evenness (relative abundance of species) of the microbiota, a decrease in Firmicutes species, and an increased abundance of members of the Enterobacteriaceae (Proteobacteria) (Morgan *et al.*, 2012). Members of the Bifidobacteria and lactobacilli have also been shown to decrease in abundance in both CD and UC (Shanahan, 2012). In UC there is also an increase in Actinobacteria, Proteobacteria and *Desulfovibrio* species (Lepage *et al.*, 2011; Rowan *et al.*, 2010). In CD patients, there was a significant decrease compared to controls in the abundance of the Clostridia class members, *Faecalibacterium prausnitzii* in particular (Fujimoto *et al.*, 2012). On the other hand there was an increase in the mucosa-associated bacterial numbers and an increase in the abundance of members of the Enterobacteriaceae, and of *Ruminococcus gnavus* (Shanahan, 2012).

Cancer

There have been several studies showing effects of the microbiota on host tumor promotion. This has been shown in various organs, including the skin, colon, liver, breast, and lungs (Schwabe and Jobin, 2013). Carcinogenesis driven by microbiota is thought to result from the presence of potentially harmful microbes or by lack of protective ones (Tlaskalova-Hogenova *et al.*, 2014). Among the proposed mechanisms for tumor promotion by microbiota are induction of inflammation and barrier failure. These can be achieved by a combination of microbial alteration encouraging growth of inflammation-inducing bacteria, mucin-degrading bacteria, genotoxic bacteria, and bacteria producing cancer-promoting metabolites that discourage growth of health-promoting symbionts such as butyrate-producing bacteria (Baxter *et al.*, 2014). Additionally, the microbiome composition can affect the abundance of specific bacterial pathogens such as *Helicobacter pylori*, which was found to be carcinogenic. Many of the studies have focused on the

potential roles of the microbiota in colon carcinogenesis. It has been shown that colon cancer patients have a distinct microbiome compared to healthy controls. In a mouse model of colon cancer, microbial composition showed increased abundance of *Bacteroides*, *Odoribacter*, and *Akkermansia* genera and decreased abundance of *Prevotellaceae* and *Porphyromonadaceae* families. GF mice receiving microbial transplants from tumor-bearing mice showed increased tumorigenesis in the colon compared to GF mice receiving transplants from healthy animals (Zackular *et al.*, 2013).

Future Microbiome Research

Microbiome research is still in its infancy. While many studies have shown correlations between disease states and alterations in the microbial populations, there are still very few studies describing the effects of specific microbes and mechanisms of action. As the microbiome includes populations of many different microbes, their interactions and environmental effects will likely be complex. It is presumed that future research will reveal precise microbial-host interaction networks and mechanisms. As part of the second stage of the HMP project, current ongoing research is focused on large-scale studies of the microbiome in human health and disease in four systems: (1) pregnancy, including those resulting in preterm birth; (2) gut disease onset, using inflammatory bowel disease (IBD) as a model; (3) respiratory viral infection; and (4) onset of type 2 diabetes (T2D). These models will likely shed more light on microbial-host interactions by integrating genomic, phylogenetic, transcriptomic, and metabolic data as well as measures of the host inflammatory and clinical state (Integrative HMP (iHMP) Research Network Consortium, 2014). Such findings will hopefully lead to effective probiotics and personalized medical treatments for a variety of conditions. To date, the only condition medically treated with fecal transplants is severe contamination by *C. difficile*. However, once the microbiome components and roles will be better understood, microbiome-based treatments including specific probiotics, prebiotics, and transplants may be developed for a variety of diseases and conditions.

Cell Biology of Virus Infection

A Helenius and Y Yamauchi, Institute for Biochemistry, Zürich, Switzerland

Viruses are best known as infectious agents that cause diseases and epidemics in humans and livestock. Unlike other infectious agents such as bacteria, they are, however, extremely small and simple in structure. The simplest among them contain one nucleic acid molecule (the viral genome) and a single protein in multiple copies forming the protective shell. Such simplicity is only possible because viruses have no metabolism, no means of locomotion, no source of energy, and no biosynthetic machinery. Their replication strategy differs completely from that of bacteria and other cells. Instead of multiplying by division, they replicate by taking over live cells and forcing them to synthesize new virus particles. The 'blueprint' is provided by the viral DNA or RNA genome, the building blocks and the biosynthetic machinery by the host cell. New virus particles are often produced in huge numbers, and serve as the vehicle for transmission of infection to further cells and organisms. The host cell generally ends up dying in the process. To understand viruses and their replication cycle, one must understand the biology of their host cells and host organisms. This is why cell biology is an important aspect of virological research and infectious disease medicine.

Our world is filled with thousands of different types of viruses. They are omnipresent, and capable of infecting all forms of life: bacteria, slime molds, plants, insects, fish, mammals, etc. Some are specific to a single host species, and may have a long common evolutionary history with their host organism. Polio-, small pox, measles, and Herpes Simplex are examples of viruses specific for humans. Other viruses can move between different organisms such as influenza A virus (IAV), yellow fever virus, and Western Equine Encephalitis virus, to name a few. The causative agent of AIDS, (human immunodeficiency virus-1) HIV-1, was originally a monkey virus.

The Virus Particle

Viruses can be classified according to several criteria. **Figure 1** shows examples of animal viruses from different virus families. Enveloped viruses have a lipid bilayer membrane; non-enveloped viruses are composed of nucleic acid and protein only. Their size varies from 25 to about 400 nm in diameter. While many viruses are spherical in shape, some are filamentous, like the Ebola virus, or bullet-shaped, like the rabies virus. A classification based on the genome, which can be DNA or RNA, and its properties (single-stranded or double-stranded, positive or negative sense, etc.), is often useful when considering the cell biology of infection.

Although different in size, shape, and overall appearance, viruses have in common that they contain a genome in the form of one or multiple molecules of DNA or RNA. The genome is present in a condensed and protected state, which together with proteins form a structure called the capsid ([Harrison, 2013](#)). One common capsid design involves hexameric and pentameric assemblies of capsid proteins. These are joined together according to rules of icosahedral symmetry to form a protein shell. This soccer ball-like architecture generates a protected space for the genome using a minimum number of different building elements.

In many non-enveloped viruses such as polio-, adeno-, and parvoviruses, the classical icosahedron-like capsid plus the genome constitute the entire virus particle. More complex viruses can, however, combine an icosahedral capsid with additional layers of protein, as well as a lipid bilayer envelope (herpes-, alpha-, and retroviruses) (**Figure 1**).

An alternative capsid structure is observed in many RNA viruses. Here numerous capsid proteins interact with the RNA over its full length forming a helical RNA/protein complex. Tobacco mosaic virus is the classical example of a

Figure 1 Animal viruses have many forms and sizes. Polyomaviruses are non-enveloped and have a naked icosahedral capsid (45 nm) with a circular dsDNA genome packaged as a minichromosome around histones. Togaviruses (alphaviruses, 70 nm) are enveloped with an icosahedral capsid with a positive-sense ssRNA that is capped at the 5' end and poly-adenylated at the 3' end. HIV-1 is enveloped (100 nm) with a conical capsid and a positive-sense ssRNA genome. Like other retroviruses, the capsid contains two copies of the genome associated with tRNA from the cell. Influenza viruses are enveloped, and can be round (80–120 nm) or filamentous with a negative-sense ssRNA wrapped around nucleoproteins and separated in 6–8 segments. Rhabdoviruses are bullet-shaped, rod-like, and enveloped (180 × 75 nm), with a genome composed of a single negative-sense ssRNA. Poxviruses are brick-shaped (300 × 250 × 150 nm) with an internal core (blue) and lateral bodies (green). The scheme shows a mature virus (MV) with one membrane. The genome is composed of dsDNA. Bar: 100 nm.

non-enveloped helical virus. Many enveloped RNA viruses that infect humans have helical capsids trapped within a lipid bilayer envelope. These include IAV, measles virus, and Rift Valley fever virus.

A single virus particle has everything needed to infect a cell. The proteins present in the particle in one or more copies are called structural proteins. Depending on the virus, the structural proteins can include – in addition to capsid proteins – enzymes such as RNA polymerases and host proteins such as histones. Nonstructural proteins are virally encoded and expressed within the infected cells, but they are not part of the mature virus particle. They are important because they have a variety of functions in nucleic acid replication, virus assembly, and in the suppression of host cell defense mechanisms. In a virus population only a minority of particles actually succeed in infecting cells.

Many of the enveloped viruses are surprisingly heterogeneous in size, shape, and composition and display rather poor infectivity if analyzed at the level of individual particles. However, it has been shown that one infectious virus particle is sufficient to infect a cell.

Transmission

The spread of virus infection occurs at several levels; from cell to cell, tissue to tissue, organism to organism, and population to population. Transmission to humans can occur via airborne droplets, direct contact, insect bites, injection needles, food items, open wounds, congenital transmission, etc. Most viruses enter through epithelial barriers (the skin, the airways, the digestive tract, etc.). Once initiated, infection may be cell type-specific and strictly localized, or the virus may spread widely and cause infection of many cell types and tissues. Many virus infections are asymptomatic and held in check by the immune system.

Introduction to the Replication Cycle

The mission of the virus particle as such is to mediate the transport of the viral genome and sometimes accessory proteins from the infected cell to a new host cell. The virus must be able to undergo proper assembly and release from the producing cells. It must protect the viral genome in the extracellular space during transit. Finally, its job is to deliver the capsid into the cytosol or the nucleus of a new host cell and release it. These are not trivial duties because they involve, for example, the transfer of large polar macromolecular assemblies through cellular membranes. In addition, they require orderly assembly and disassembly of the particle.

Either in the cytosol (for most RNA viruses) or the nucleus (for most DNA viruses), the uncoated genome is used for the synthesis of viral mRNAs and replication of new viral genomes, leading to amplification of viral components in the cell (Whelan, 2013). Enough viral components to assemble thousands of new virus particles (nucleic acids, proteins, glycoproteins, and lipids) have to be synthesized. The components are often generated in different locations inside the cell. The logistics of bringing them together for genome packaging, particle assembly, intracellular trafficking, and release is

complicated. The process often involves many cellular compartments and numerous viral and cellular factors. The high degree of dependence on the host cell in all stages of infection from entry to release is one of the reasons why cell biology is so important for understanding the life-style of viruses.

Virus Entry

Like most of the steps in the replication cycle, virus entry is critically dependent on assistance by the host cell. The virus needs receptor expression, membrane traffic, signal transduction, cytoskeleton motility, nuclear import, etc. As illustrated in Figure 2, the process of entry occurs in several steps. The majority of viruses make use of the endocytic machinery to enter cells (Mercer and Helenius, 2009; Mercer *et al.*, 2010; Yamauchi and Helenius, 2013). This strategy offers advantages including a free ride on the cytoskeleton from the surface to the perinuclear region inside endosomal vesicles. Passage through the crowded, obstacle-rich cytoplasm is thus made easy. By having the penetration step occur from intracellular vacuoles, the exposure of tell-tale viral components on the plasma membrane is minimized, which helps to delay detection by antibodies and immune cells. There are, however, some enveloped viruses that can fuse directly with the plasma membrane. In addition to HIV-1 and some other retroviruses, these include members of the herpes- and paramyxovirus families (Jardetzky and Lamb, 2014; Eisenberg *et al.*, 2012; Klasse, 2012).

After internalization by endocytosis, viruses are sorted into a network of endocytic vacuoles that comprise a dynamic, interacting collection of organelles that the cell uses to deal with the incoming vesicle traffic of different cargo molecules and hundreds of signaling receptors. Penetration of viruses into the cytosol generally occurs through the limiting membranes of endosomes or macropinosomes often triggered by low pH and/or proteolytic activation of viral proteins. By providing such biochemical cues, the endocytic organelles inadvertently ‘inform’ the incoming particles when and where it is time to enter the cytosol. Viruses that fail to respond correctly to these signals are delivered to lysosomes and eventually degraded.

The entry program is completed only when the viruses or viral capsids have reached a final destination in the cytosol or nucleus, and the genome has been uncoated so that it can be used as template for mRNA production or genome replication. The uncoating process often occurs in several steps at different stages during the entry process (Suomalainen and Greber, 2013).

The details of virus entry are highly variable depending on virus and cell type. However, the overall profile of events is similar for most viruses. The major steps will be discussed below without going into great detail.

Receptor Binding

Attachment of virus particles to the cell surface occurs by the interaction of viral proteins with cell surface proteins or carbohydrates. In enveloped viruses, binding to surface molecules occurs through specific envelope glycoproteins. Non-

Figure 2 Stepwise host cell entry of animal viruses. When viruses enter, they follow a stepwise program that allows them to travel from the extracellular space to the site of replication in the cytoplasm or the nucleus of the host cell. Entry begins by binding to receptors on the cell surface and by lateral diffusion of viruses along the membrane. Receptor association and clustering activate signaling cascades that trigger endocytic internalization of virus particles. The viruses move into the cytoplasm as cargo particles inside endocytic vesicles and vacuoles. Cellular cues, such as low pH in these vacuoles, triggers changes in the virus particles or in viral proteins that activate membrane fusion or other mechanism of penetration into the cytosol. After penetration, some viral capsids stay in the cytosol where they undergo uncoating and replication. Others use the microtubule transport and nuclear import machineries to reach and enter the nucleus. Some enveloped viruses can enter cells directly by fusing with the plasma membrane. The details in the entry program vary for different viruses and cell types, but many of the key steps shown here are general. Modified from Marsh and Helenius (2006).

enveloped viruses usually bind through sites in the virus shell unless – as in the case of adenoviruses – specialized antennae are present (Grove and Marsh, 2011).

The binding partners on the cell surface are called ‘viral receptors,’ although their reason for being there has to do with normal cellular functions. Hundreds of different receptors for viruses have been identified. The list includes receptors for physiological ligands such as the transferrin receptor,

components of the extracellular matrix, surface antigens of the immunoglobulin family, ion channels, receptor tyrosine kinases, glycoproteins and proteoglycans. Viruses of the polyoma virus family have evolved to bind specifically to the glycan moieties of specific gangliosides, thus generating raft-like domains enriched in cholesterol and sphingolipids, activating an unusual endocytic trafficking pathway to the ER (Tsai and Qian, 2010; Qian *et al.*, 2009). Receptor-binding is often specific and therefore important in defining the tropism of viruses as well as eventually determining the type of disease.

By binding to CD4 and a cytokine receptor (Figure 3), HIV-1 is an example of viruses that need more than one receptor type to enter cells. In this case, the two receptors trigger a conformation change in the viral glycoprotein that activates its membrane fusion activity (Klasse, 2012). To be able to infect a variety of cell types and use different entry pathways, herpes simplex virus type 1 (HSV-1) carries multiple receptor-binding glycoproteins with different specificity (Eisenberg *et al.*, 2012).

Compared to most cellular ligands, viruses are large and multivalent. By binding simultaneously to many receptors, they can generate a patch or domain in the plasma membrane with unique composition and properties (Szklarczyk *et al.*, 2013). This can in turn result in trans-bilayer signaling, coat assembly on the cytosolic side, and changes in lateral mobility.

Live cell imaging of fluorescent virus particles has shown that immediately after attachment most virus particles are motile on the surface of cells. Some surf on filopodia propelled in the direction of the cell body by dynamic actin flow; others undergo random or directed movement on the cell body itself (Lehmann *et al.*, 2005; Burckhardt and Greber, 2009; Schelhaas *et al.*, 2008). Typically, the movement stops before the viruses are internalized by endocytosis. Several viruses have been shown to induce formation of clathrin coats and vesicles at the site of binding (Cureton *et al.*, 2010). Thus, they are capable of triggering their own endocytic internalization.

Signaling

Viruses are known to activate cellular signaling pathways and thus trigger a variety of changes in the cell, such as ruffling of the plasma membrane and endocytosis through macropinocytosis and other mechanisms. Some do this by interacting directly with signaling receptors, others by indirectly carrying phosphatidylserine (PS) in their envelope membrane. When exposed, this negatively charged phospholipid activates receptors, signaling pathways, and endocytic mechanisms that are normally reserved for uptake of residual bodies left behind after apoptotic cell death. In this way, pox- and filoviruses use ‘apoptotic mimicry’ as their strategy to enter cells (Mercer and Helenius, 2008, 2012; Moller-Tank *et al.*, 2013). Other viruses activate other signaling pathways.

Endocytosis and the Endosome Network

Many of the mechanisms of endocytosis known to cell biologists are exploited by viruses depending on particle size, receptor choice, and cell type (Figures 4 and 5). The clathrin-mediated pathway is commonly used by small and medium

Figure 3 Attachment factors and receptors. Cell surface proteins, lipids, and carbohydrates can serve as virus attachment factors and receptors. This schematic shows examples of virus receptors and viruses that can bind to them. Some viruses such as adenoviruses 2 and 5 as well as HIV-1 require more than one receptor. mPy, mouse polyoma virus; KSHV, Kaposi's sarcoma-associated herpesvirus; HSPG, Heparan sulphate proteoglycan; LDL-R, low-density lipoprotein receptor; DC-SIGN, dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin; CAR, coxsackievirus and adenovirus receptor; CCR and CXCR, chemokine receptor.

Figure 4 Endocytic entry pathways for animal viruses. The majority of viruses use endocytosis for entry. For this, they take advantage of different endocytic mechanisms. Many viruses of small and intermediate size (40–200 nm) use clathrin-mediated endocytosis (CME), or caveolar and lipid raft-mediated mechanisms involving tight-fitting vesicles. CME and caveolar uptake are dynamin-dependent (green beads). The virus virus-carrying vesicles and vacuoles often move along microtubules. The endocytic network that the viruses enter after internalization is composed of a large variety of interacting membrane compartments many of which are acidic. The low pH and other cues trigger the penetration in different organelles depending on the virus and its properties. As shown by the thick gray arrows, penetration can happen in early, maturing, and late endosomes as well as in the ER and possibly the Golgi complex. Viruses that use macropinocytosis – an actin-dependent transient process that involves membrane ruffling and fluid uptake into large vacuoles – penetrate from macropinosomes. Micropinocytosis represents an actin-dependent, dynamin-independent endocytic mechanism, which is still incompletely characterized. The names of some of the viruses using different pathways are indicated. Some viruses such as influenza A virus can exploit multiple pathways. Dotted arrows indicate vesicle maturation.

sized viruses (up to about 150 nM in diameter) macro-endocytosis by larger ones (Chigo, 2010; Mercer *et al.*, 2010). Some of the pathways discussed in the endocytosis chapters such as the CLIC/GEEC pathway do not seem to be used by

viruses. Most endocytic events are activated by viruses themselves either by triggering signals or by inducing plasma membrane indentation. After binding to its receptor, the GM1 ganglioside, SV40 has been shown to induce the formation of

Figure 5 Alphaviruses are internalized by clathrin-mediated endocytosis. Semliki Forest virus, a member of the alphavirus family, is a small, enveloped, arthropod-borne RNA virus that enters host cells by clathrin-mediated endocytosis. After binding to the plasma membrane, it induces the assembly of a clathrin coat on the cytosolic surface of the plasma membrane. After about 1 min, the clathrin-coated pit is completed. It undergoes membrane fission, and the virus is internalized in a coated vesicle. Different stages of this process are shown in electron micrographs taken by Jürgen Kartenbeck and Ari Helenius.

a deep, tight-fitting pit in the plasma membrane, as if budding into the cell (Ewers *et al.*, 2010). Cellular factors are responsible for membrane fission resulting in a vesicle for transport to endosomes. This process is interesting because the cargo virus is here inducing membrane curvature by a zipper-like process when it binds to multiple GM1 gangliosides.

After endocytosis, many viruses are first delivered to early endosomes (EE) (Helenius, 2013). If penetration does not happen in the EEs, they generally move within maturing endosomes and late endosomes (LE) toward the perinuclear region to be delivered to endolysosomes (Figure 4). Viruses that enter via macropinocytosis or related pathways bypass the EEs and join the classical endosome pathway at the level of LE or endolysosomes. It has been proposed that some viruses enter recycling endosomes, autophagosomes, and the Golgi complex before penetration.

Late-penetrating viruses, such as IAV and bunyaviruses, are dependent on endosome maturation for infection. This means that their entry can be inhibited by perturbations that affect microtubule-mediated vesicle traffic, Rab conversion, formation of intraluminal vesicles, etc. Polyomaviruses travel from LEs to the smooth ER where penetration through the ER membrane into the cytosol occurs with the help of ER chaperones and components of the quality control and ERAD pathways (Inoue and Tsai, 2013).

Penetration

Where exactly the critical penetration steps occur often depends on pH, because exposure to low pH triggers changes in many viruses that make them penetration-competent (White *et al.*, 1980, 1982). Depending on the pH-threshold for such activation, the penetration reaction may occur in EEs (pH 6.5–6.0), in LEs or endolysosomes (pH 6.0–5.0), or in macropinosomes (Figures 4 and 6). However, there are other intracellular triggers such as proteolytic processing of viral proteins, exposure to specific vacuolar proteins, assistance by cytosolic factors, etc. For enveloped viruses, large conformational changes in the fusion glycoproteins of the viral envelope lead to hydrophobic attachment to the endosomal target

Figure 6 Incoming alphaviruses in endosomes. The low pH in early endosomes induces a dramatic, irreversible conformational change in the spike glycoproteins triggering their membrane fusion activity. The viruses fuse from the inside with the limiting membrane of the endosome, and the icosahedral capsids (see arrow heads) are released into the cytosol. Moments later the capsids are uncoated and the RNA begins to be translated. The image is by Jürgen Kartenbeck and Ari Helenius.

membrane, followed by fusion of the viral envelope (Kielian and Rey, 2006; Harrison, 2013). The fusion proteins have been analyzed in great detail. They belong to three different general classes. As a result of membrane fusion, the capsids are transferred into the cytosol.

While the penetration of non-enveloped viruses is less well understood, it is evident that there are several options. The viruses can escape by lysing endosomal vacuoles, they can induce the formation of pores through which the virus itself or just the genome can pass into the cytosol, or – as in the case of SV40 – they can make use of the ERAD pathway in the ER (Suomalainen and Greber, 2013; Cerqueira and Schelhaas, 2012).

Intracellular Transport and Nuclear Import

Replication of viruses occurs either in the nucleus or in the cytoplasm. In the cytoplasm, it is usually associated with membranes, granules, and complex virus-induced structures

Figure 7 Entry into the nucleus. Viruses that replicate in the nucleus must transport their genome and sometimes accessory proteins across the nuclear membrane. Some of the mechanism and viruses that use them are shown. Subviral complexes of papillomaviruses wait in the cytosol until cell division breaks down the nuclear membrane barrier. The ribonucleoprotein complexes (vRNP) of influenza virus are imported through nuclear pores. Herpesvirus capsids dock at the cytosolic side of the nuclear pore and inject their genome into the nucleus. Adenovirus capsids are disassembled on the cytosolic side of the nuclear pore, and the genome is released into the nucleus. Hepatitis B capsids are small enough to be imported through to the nuclear pore complex. Uncoating of the viral DNA occurs on the inside in the nuclear basket.

serving as virus factories. To reach the sites of replication, intracellular transport of incoming viruses and capsids is required. Viruses often make use of microtubules and microtubule-dependent motors (Figure 2). For example, the transport of herpesvirus capsids from their site of penetration in the axons to the nuclear pores of neurons involves such minus end-directed movement. Specific viral proteins attach to dynactin, which mediates attachment to the dynein motor (Radtke *et al.*, 2010; Smith, 2012). Adenoviruses use a similar strategy (Kelkar *et al.*, 2004). Viruses also bind to kinesins that serve as plus end-directed motors.

Viruses that enter the nucleus must be able to overcome another barrier, the nuclear envelope (Figure 7). Most of the viruses have nuclear import signals and make use of the cell's nuclear import machinery. If small enough in diameter (< 40 nm), they can use this machinery to enter through the nuclear pore complex and uncoat inside the nucleus (polyomaviruses and hepatitis B virus) (Rabe *et al.*, 2003). They can also release the genome through the NPC without entering the nucleus (herpes- and adenoviruses) (Sodeik *et al.*, 1997; Greber *et al.*, 1997). In influenza virus, the RNA genome is present in short pieces individually packaged in particles small enough to enter through the nuclear pore complex (Cros and Palese, 2003).

Viruses can also cause local lysis of the nuclear envelope (parvoviruses) (Cohen *et al.*, 2011), or they can wait in the cytosol until mitosis occurs and the nuclear envelope is temporarily disassembled (papilloma- and retroviruses) (Aydin *et al.*, 2014; Suzuki and Craigie, 2007).

Replication and Synthesis of Viral mRNAs

The molecular biology of virus replication and mRNA production depends on the type of genome (DNA or RNA, single-stranded or double-stranded, etc.). A lot of information is available for many different viruses and virus families. Here, a

short review of some cell biologically relevant aspects of these important processes will have to suffice.

DNA and RNA viruses have a different set of options. DNA viruses can make use of the cell's DNA synthesis and transcription machinery as well as accessory functions such as mRNA splicing and processing in the nucleus. Therefore, with few exceptions, the replication of DNA viruses occurs in the nucleus.

Although profiting from cellular services in the nucleus, these viruses have to deal with the added problem of import/export across the nuclear envelope. This applies not only to incoming virus particles but also to viral protein components needed for capsid assembly. These are synthesized in the cytosol, then transported into the nucleus for virus assembly. The proteins in question therefore have nuclear localization signals and make use of the nuclear import machinery of the cell. To exit from the nucleus, non-enveloped viruses usually wait for the cell to die and the nuclear envelope and the plasma membrane to lyse.

The newly assembled capsids of herpes viruses escape into the cytosol by a complicated two-step membrane fission/fusion strategy that allows the icosahedral capsids assembled in the nucleus to cross the two membranes of the nuclear envelope (Figure 8). By undergoing a second budding event into the Golgi complex, they acquire their final membrane envelope before being secreted into the extracellular space (Mettenleiter, 2004).

Influenza virus belongs to the few RNA viruses that replicate in the nucleus. Individual viral ribonucleoproteins assembled in the nucleus are escorted through nuclear pore complexes by viral and cellular proteins to the cytosol and transported to the plasma membrane where they join up with viral glycoproteins and bud out (Cros and Palese, 2003).

Since cells do not have RNA-dependent RNA polymerases, RNA viruses must provide their own enzymes for genome replication and mRNA synthesis. With a few exceptions, they have evolved to replicate in the cytoplasm. If the RNA genome is single-stranded and has a positive sense, it can be used

Figure 8 Nuclear exit and maturation of herpes simplex virus 1 and influenza A virus. Left: After capsid assembly and DNA encapsidation in the nucleus, the icosahedral HSV nucleocapsids (green) together with some tegument proteins (yellow) bud into the inner nuclear membrane in a process called primary envelopment, followed by fusion with the outer nuclear membrane. Next the nucleocapsids associate with additional tegument proteins (orange) and bud into the Golgi-endosome compartment (secondary envelopment) acquiring a new envelope membrane and mature glycoproteins derived from the endoplasmic reticulum (ER). The virion is released from the cell by exocytosis. Right: Newly assembled vRNPs of influenza virus bind to two soluble proteins, M1 and NEP, and exit to the cytosol through the nuclear pore complex. In the cytosol, the vRNP traffic along microtubules to the plasma membrane where they are encapsidated in a shell of M1 protein. A budding reaction follows because the assembled cores interact with the ER-derived viral glycoproteins that have been transported to the cell surface.

directly as a messenger RNA to translate proteins. The required RNA polymerase needed to replicate the viral RNA and generate additional messenger RNAs for viral proteins can now be synthesized with the incoming RNA as messenger. If the RNA genome has negative sense – as often is the case among animal RNA viruses – the required enzymes must be brought along as a structural component of the incoming virus.

Replication and mRNA synthesis usually occur in close contact with cytoplasmic membranes where the process is harder to detect by cellular defense systems that detect double-stranded RNA. The cell biological consequence is that virus infection causes major rearrangements in membranes of infected cells, leading to so-called cytopathic effects. Some RNA viruses induce a shut-off of host protein synthesis, others enhance the formation of stress granules and P-bodies, while many induce apoptosis and cell death (Onomoto *et al.*, 2014; Clemens, 2005). The cell biological consequences of infection are often dramatic. Virus infection does not, however, always have to

result in cell death, because there are many viruses that induce latent and persistent infections (Speck and Ganem, 2010).

Virus Assembly and Release

The components needed for assembly of new particles include, in addition to the viral genome, the protein components of the capsid and envelope, enzymes such as polymerases, and the lipid bilayer in the case of enveloped viruses (Perlmutter and Hagan, 2014). Host cell proteins are also sometimes included such as histones, ubiquitin, molecular chaperones, or even ribosomes. Through the glycans present in envelope glycoproteins and the lipids, the virus particles possess an ‘imprint’ of the host that they are derived from. This has consequences, for example, when dendritic cells in the skin recognize insect-derived virus particles as ‘foreign’ by the N-linked glycans that the glycoproteins carry (Freer and Matteucci, 2009).

Figure 9 Virus budding at the plasma membrane. Like other alphaviruses and many other enveloped viruses, Semliki Forest virus buds at the plasma membrane of infected cells. The icosahedral capsid that contains the viral RNA genome is assembled in the cytosol. It is then transported to the plasma membrane where it interacts with the cytosolic domains of the glycoproteins. These interactions drive the progressive generation of membrane curvature around the capsid and eventually the membrane fission event that releases the mature particle. The image is by Jürgen Kartenbeck and Ari Helenius.

As already mentioned, the components of the virus are usually synthesized and modified in different compartments of the cell: lipids in the ER and Golgi, envelope proteins in the ER, nucleic acids in the nucleus or cytosol, and capsid proteins in the cytosol. How the components are brought together locally and how they assemble to generate virus particles is a complex process that varies between virus families (Perlmutter and Hagan, 2014). Like entry and uncoating, the assembly process relies on both cellular and viral factors. The formation of icosahedral capsids depends mainly on the properties of the capsid proteins, and how they can assemble into pentons and hexons.

The selective inclusion of viral RNA and DNA in the particle is typically determined by a sequence element (a so-called packaging sequence) in the viral genome recognized by one or more of the capsid proteins. The viral genome may be introduced into an almost completed capsid through one of the vertices, or it may have to be present before capsid assembly can even start. In the case of viruses with a negative sense genome, capsid proteins bind to the RNA already when it is being synthesized by the viral polymerase in the cytosol or the nucleus. The genomic RNA of these viruses therefore never exists in a completely uncoated state.

The viral glycoproteins are synthesized, modified, and folded in the ER as integral membrane proteins. Most of them are type I integral transmembrane proteins with large oligomeric ectodomains. Like cellular proteins, they undergo glycosylation, glycan trimming, disulfide oxidation, oligomerization, chaperone interaction, and quality control in this compartment. They then either stay in the ER (flaviviruses) or move along the secretory pathway to the Golgi complex (bunya- and herpesviruses) (Figure 8), the plasma membrane (most other enveloped viruses), or possibly the endosome membrane. For transport and targeting they possess the appropriate sequence signals and undergo similar posttranslational modifications as cellular membrane proteins. Influenza hemagglutinin and HIV-1 glycoprotein are often used as model proteins for analyzing the biogenesis, folding, quality control, and vesicular transport of glycoproteins.

With the exception of pox viruses, the final assembly of capsids and envelopes involves a budding reaction. The envelope proteins, capsids, and in some cases matrix proteins

with adaptor functions establish a network of interactions with the exclusion of most host proteins, and form an outward oriented bud in the membrane (Figures 8 and 9). When the membrane in the bud closes and undergoes fission, a fully membrane-enclosed particle is formed; this is the enveloped virus. For some enveloped viruses such as HIV-1, the fission reaction depends on components of the ESCRT complex, which localize to the bud neck (Martin-Serrano *et al.*, 2001). After budding, the virus particle may undergo some further maturation steps. A network of interactions between viral components makes the virus resistant enough to withstand stresses in the extracellular environment. However, the design of the particle is such that it provides for metastability, and thus the ability to uncoat and release the genome when the virus enters a new host cell. The envelope serves as an extracellular transport vesicle poised to fuse with a membrane in the new host cells, as already discussed.

While the lipid composition of the viral envelope membrane reflects the cellular membrane where budding occurred, it may be enriched in certain lipids such as those present in lipid rafts. The matrix proteins located between the envelope and the capsid often serves as important adaptors in the budding process connecting the membrane proteins with the capsid. If budding occurs at the membranes of cytoplasmic organelles (herpes-, flavi-, retro-, and bunyaviruses) (Garoff *et al.*, 1998), the particles formed are secreted into the extracellular space via the secretory pathway (Figure 8).

Virus Factories and Mini-Organelles Generated for Virus Replication

Introduction

Viruses are relatively simple life forms which use a protein capsid to carry short stretches of genomic material from one cell to another. All viruses are obligate intracellular parasites and need to enter cells to replicate. Nucleic acid genomes delivered to the cytoplasm provide a template to generate new genomes which in turn initiate the synthesis of mRNA that encode viral proteins. These processes require the assembly of complex replication machines that ensure that genome replication and packaging are carefully coordinated. For many viruses this is achieved by concentrating virus genomes, replicase proteins, and the host proteins required for replication in a 'mini-organelle' called a virus factory or 'viroplasm' (Netherton *et al.*, 2007; Fernandez de Castro *et al.*, 2012).

All viruses synthesize mRNA and use host ribosomes to make viral proteins. Viruses are grouped into the 'RNA' or 'DNA' viruses according to the nature of their genome. The (+) strand genomes make an mRNA that is immediately translatable, and the complementary RNA or DNA sequence is called negative (−) strand. This means that the genomes of (+) strand RNA viruses can function as mRNA while the (−) strand RNA viruses need to be delivered into the cell with an RNA-dependent RNA polymerase (RdRp) that uses the negative template to make the (+) strand. In both cases virus replication occurs in association with cytoplasmic organelles and (+) RNA is translated by ribosomes into protein. The genomes of most DNA viruses are made from double-stranded DNA and most DNA viruses replicate in the nucleus because they need to recruit host proteins for DNA replication. The DNA viruses also show temporal gene expression with genes being expressed at early, intermediate, and late times during infection. Early genes are expressed before the onset of replication while late genes are normally used for replication and assembly. The small DNA viruses, for example, polyoma and papillomaviruses have limited coding capacity and do not make their own DNA-dependent DNA polymerase (DdDp). The large DNA viruses, for example herpes viruses and poxviruses encode their own DdDp, but the herpes viruses still rely on nuclear factors for genome replication. Interestingly, the poxviruses encode all the enzymes needed for DNA and mRNA synthesis, and replicate in the cytoplasm.

Evolution has not been blind to viral infection and cells make several proteins that recognize viral genomes as danger signals because they are different from host DNA or RNA. The RNA viruses are a good example because replication of RNA from an RNA (rather than DNA) template generates a double-stranded RNA (dsRNA) intermediate that is not generated by the host cell. Recognition of dsRNA in plants, insects, and other primitive animals results in gene silencing while in vertebrates this leads to activation of interferon (Randall and Goodbourn, 2008). Cells also contain sensors for viral DNA that activate

proinflammatory responses (Rathinam and Fitzgerald, 2011). The concentration of replicase proteins within virus factories would be expected to provide a potent signal for activation of these defenses. Viruses have overcome this problem by using virus factories to shield replication intermediates from recognition by nucleic acid sensors, but at the same time the factories retain connections to the cytoplasm to allow export of nucleic acid to sites of genome packaging.

RNA Viruses

(+) Strand RNA Viruses Generate Mini-Organelles from Membranes Derived from the Secretory Pathway

The genomes of the (+) strand RNA viruses encode a single polyprotein synthesized by cellular ribosomes. The capsid proteins and the nonstructural proteins required for replication and are generated from the polyprotein by viral, and sometimes host, proteases. In each case nonstructural proteins with hydrophobic domains act as a scaffold to target the RdRp to the cytoplasmic face of membrane-bound organelles where assembly of the replicase complex induces membrane curvature (reviewed Cottam *et al.*, 2009; den Boon *et al.*, 2010; den Boon and Ahlquist, 2010). These remodeled membranes vary greatly between different families of (+) strand RNA viruses but are thought to be formed by similar mechanisms where their dimensions are determined by the assembly of the replicase proteins during invagination. This process is analogous to the way that virus capsids vary in size and shape depending on the assembly of capsid subunits (Ahlquist, 2006).

Spherules produced by the *Togaviridae* and *nodaviruses*

The mammalian alphaviruses, for example, Semliki Forest virus (SFV), Sindbis virus (SINV), and the rubivirus rubella virus are members of the 'Togaviridae' and encode a single polyprotein called nsP1234 that contains the helicase, methyltransferase, and RdRp. Proteolytic processing releases the RdRp (P4) which binds to P1,2,3 and is targeted to membranes by a hydrophobic domain in P1 (Figure 1(a)). The structural proteins are generated as a second polyprotein encoded by a sub-genomic message which is formed when the RdRp transcribes RNA from an internal initiation site. A signal sequence exposed after removal of the capsid protein directs synthesis of envelope proteins by ribosomes attached to the endoplasmic reticulum (ER). The 'Togaviridae' generate large 'cytopathic vacuoles' with 50 nm diameter invaginations called spherules aligned along the inside face of the vacuole. The vacuoles contain replicase proteins and are derived from endosomes and lysosomes. Spherules can be generated from many different membrane-bound organelles. Flock house virus, an insect virus, generates spherules in the outer

Figure 1 Formation of spherules during replication of alphaviruses. (a) The alphaviruses encode a single polyprotein called nsp1234 that contains the helicase, methyltransferase, and RdRp. Proteolytic processing releases the RdRp (P4) which is targeted to membranes by a hydrophobic domain in P1 (i). The structural proteins (ii) synthesized as a second polyprotein (C,E2,6K,E1) are directed by ribosomes to the endoplasmic reticulum. Assembly of replicase proteins induces membrane curvature and invagination forming a spherule (iii). The interior of each spherule is connected to the cytosol by a thin membrane neck that surrounds a channel wide enough to allow passage of (+) RNA into the cytosol allowing assembly with capsid proteins (iv). In the case of Bromovirus and tombusvirus, ESCRT proteins (green) recruited to the spherule by replicase proteins stabilize the membrane neck and prevent closure of the spherule. (b) Spherules generated in mitochondria by flock house virus. Electron micrographs (i) generated from a tilt series were processed digitally to generate the tomogram in (ii). (c) A 3D reconstruction of spherules shows the likely organization of replicase proteins of flock house virus modeled as 7 nm diameter spheres (green) lining the inner surface of the spherule. Reproduced from Kopek, B.G., Perkins, G., Miller, D.J., Ellisman, M.H., Ahlquist, P., 2007. Three-dimensional analysis of a viral RNA replication complex reveals a virus-induced mini-organelle. *PLoS Biology* 5, e220.

membrane of mitochondria (Figures 1(b) and 1(c); Miller *et al.*, 2001) while Brome mosaic virus, a plant virus, generates spherules in the ER. In each case the spherules are of similar size and contain approximately 100 copies of the replicase protein packed along the inner membrane surface (Kopek *et al.*, 2007). The interior of each spherule is connected to the cytosol by a thin membrane neck that surrounds a channel wide enough to allow passage of (+) RNA into the cytosol allowing assembly with capsid proteins. Spherule formation involves the assembly of replicase proteins on the cytoplasmic face of membrane-bound organelles where they induce negative curvature forcing membrane to invaginate into the organelle. Multivesicular body formation is topologically similar where ESCRT (endosomal sorting complex required for transport) proteins assemble on the cytoplasmic face of endosomes generating vesicles that bud away from the

cytoplasm into the endosome. Recent work has shown that proteins of the ESCRT-III complex are required for proper formation of spherules where they may drive spherule closure and at the same time maintain the channel that allow genomes to pass into the cytosol (Barajas *et al.*, 2014; Diaz *et al.*, 2015).

Convolved membranes and membrane webs generated by coronaviruses and flaviviruses

The flaviviruses, for example, yellow fever virus, West Nile virus, and hepatitis C (HCV) also generate a single polyprotein that, in common with picornaviruses, is processed to generate structural and nonstructural proteins (Figure 2(a)). The flaviviruses are enveloped viruses and the initial processing of the polyprotein exposes signal sequences that direct synthesis and processing of the polyprotein by the ER. The NS5B protein at

Figure 2 Formation of double-membraned vesicles by flaviviruses and coronaviruses. (a) The flaviviruses polyprotein encodes the capsid protein (C), envelope proteins (E1, E2) and the nonstructural proteins (NS2–NS5) required for replication. (i) Removal of the capsid protein by the NS2 protease exposes a signal peptide that directs synthesis of envelope proteins by the ER. (ii) Hydrophobic domains in NS4A, NS4B, NS5A and NS5B direct posttranslational insertion into the cytoplasmic face of the ER. (iii) NS5B is the RdRp. Assembly of replicase proteins induces ER invaginations and double membrane vesicles (DMV) and membraneous webs, also known as vesicular packets (VP). (b) Endoplasmic reticulum (ER) invaginations generated during dengue virus infection. Electron micrographs generated from a tilt series (top) were processed digitally to generate the tomogram (bottom). The 3D reconstruction shows the likely organization of ER invaginations. The arrow indicates viruses that may receive genomes from ER invaginations during assembly and envelopment. Reproduced from Welsch, S., Miller, S., Romero-Brey, I., *et al.*, 2009. Composition and three-dimensional architecture of the dengue virus replication and assembly sites. *Cell Host & Microbe* 5, 365–375. (c) The coronavirus polyprotein has the same overall organization as the flaviviruses but encodes as many as 15 nonstructural proteins. The figure shows double membrane vesicles and vesicular packets generated from the ER during SARS coronavirus infection. Electron micrographs generated from a tilt series were processed digitally to generate the tomogram. The 3D reconstruction shows the likely organization of interconnected DMVs (gold and silver) and vesicular packets (orange). Reproduced from Knoops, K., Kikkert, M., Worm, S.H., *et al.*, 2008. SARS-coronavirus replication is supported by a reticulovesicular network of modified endoplasmic reticulum. *PLoS Biology* 6, e226.

the C-terminus of the polyprotein is targeted to the cytoplasmic face of the ER by hydrophobic domains in NS4A, NS5A, and NS5B. The flaviviruses generate 80–100 nm diameter invaginations into an ER membrane connected to spherical vesicles and convoluted membranes (Figure 2(b)). These invaginations are less well organized than spherules, even so the spherical vesicles contain the viral polymerase and dsRNA and each has a pore opening to the cytosol that could allow exit of viral RNA for packaging with capsid proteins and envelopment (Welsch *et al.*, 2009; Romero-Brey *et al.*, 2012). The genome of the coronaviruses (CoV) is similar in organization to the flaviviruses, but these viruses are the most complex of the (+) strand RNA viruses and encode as many as 15 non-structural proteins. Severe acute respiratory syndrome coronavirus (SARS-CoV) induces double membrane vesicles (DMVs) that are between 150 and 300 nm diameter connected to the ER (Figure 2(c); Knoops *et al.*, 2008). The infected cells also contain convoluted tubular and reticular membranes, and later during infection ‘vesicular packets’ appear where vesicles are surrounded by a common outer ER membrane (Knoops *et al.*, 2008). It is thought that replication occurs in the convoluted membranes and that genomes are transported to vesicular packets for envelopment and budding.

Membrane tubes and DMVs generated by picornaviruses

DMVs formed by membrane rearrangement

Picornaviruses, for example poliovirus, coxsackievirus, foot and mouth disease virus (FMDV), and the rhinoviruses that cause the common cold generate a single polyprotein that encodes the structural and nonstructural proteins (Figure 3(a)). This is cleaved by the viral protease 3C^{Pro} to generate capsid proteins from VP1–4 and replicase proteins from 2ABC and 3ABCD. The RdRp is encoded by 3D^{Pol} which is targeted to membranes by hydrophobic domains in 3A, 2B, and 2C. Picornaviruses generate large numbers of membrane vesicles which vary between 200 nm and 400 nm diameter and some have double membranes (DMVs) while others have single membranes. These DMVs were observed in the first electron micrographs generated from cells infected with viruses in the 1960s (Dales *et al.*, 1965) and their precise origins are still in dispute. The sizes and relative numbers of vesicles vary greatly between picornaviruses families and it is not clear whether single or DMVs house the RNA polymerase. For enteroviruses, such as poliovirus and coxsackievirus, replication may take place on tubular membranes generated during the log phase of virus production, and these may be seen as single membrane vesicles in cross section in electron micrographs (Limpens *et al.*, 2011; Belov *et al.*, 2012). Single membrane tubes may gain curvature following progressive assembly of replicase proteins or through recruitment of reticulon proteins (see below) leading to formation of DMVs (Figure 3(a)). The DMVs generated during picornavirus replication lack an obvious opening to the cytosol making it possible that they seal and are a by-product of replicase assembly and used to store viral RNA.

Double membrane autophagosomes

The DMVs seen in cells infected with enteroviruses may be formed from autophagosomes. Autophagosomes are generated by a membrane trafficking pathway called autophagy that

delivers portions of the cytosol to lysosomes for degradation. Autophagy is activated during many viral infections and capture by autophagosomes can lead to destruction of viruses in lysosomes. It was therefore a surprise when it was discovered that poliovirus benefits from autophagy, with virus yields increasing some 10-fold when autophagy is activated during infection (Jackson *et al.*, 2005; Wileman, 2006). The poliovirus replicase proteins associate with autophagosomes during infection and co-expression of 2BC and 3A in cells generates autophagosomes and DMVs (Schlegel *et al.*, 1996; Suhy *et al.*, 2000). It is currently believed that poliovirus 2BC and 3A activate autophagy during infection allowing replication to take place on the surface of autophagosomes. The enteroviruses infect via the gastrointestinal tract and are resistant to acid pH and proteases. It is likely that they can survive in lysosomes and there is evidence that low pH promotes maturation of the poliovirus capsid before release from cells by exocytosis (Richards and Jackson, 2012). Autophagosomes are used as sites of assembly for the replicases of other picornaviruses such as coxsackieviruses, human enterovirus 71, and encephalomyocarditis, but the role played by lysosomes during virus release is less clear. Unlike the enteroviruses, FMDV is very susceptible to low pH and this facilitates disassembly of the virus during endocytosis and cell entry. This sensitivity to low pH makes it unlikely that the FMDV would survive in autophagosomes or lysosomes. Autophagy is, however, activated during FMDV infection but this takes place early during infection before the nonstructural proteins are synthesized, and can be activated by empty capsids and UV inactivated viruses that cannot replicate (Berryman *et al.*, 2012). It is thought that FMDV capsids activate autophagy during cell entry and this is consistent with the co-localization of capsid proteins with autophagosomes.

Host cell contribution to membrane rearrangements

The assembly of replicase proteins during spherule formation induces negative curvature resulting in a membrane invagination that moves away from the cytosol into the organelle. The formation of DMVs may require additional proteins because the generation of the outer membrane requires induction of positive curvature, allowing the curved face of the DMV to extend into the cytoplasm. The positive curvature of ER tubes is maintained by a family of proteins called reticulons which have hydrophobic domains that insert into the outer leaflet of the phospholipid bilayer (Diaz and Ahlquist, 2012; Tang *et al.*, 2007). The picornavirus 2C proteins that provide a scaffold for the 3D^{Pol} polymerase and target the replicase complex to membranes bind reticulon proteins and replication is reduced in the absence of reticulons. Most DMVs are derived, at least in part, from the ER, making it possible that reticulons play a key role in the formation of DMVs.

The lipid composition of membranes is also important for the replication of many different (+) strand RNA viruses and they are inhibited by drugs that block fatty acid and sterol synthesis (Castorena *et al.*, 2010; Kapadia and Chisari, 2005; Perez *et al.*, 1991; Rassmann *et al.*, 2007). Lipids can also provide sites for assembly of replicase complexes. The RdRp (3D^{Pol}) of poliovirus and coxsackievirus, for example, binds phosphatidylinositol-4-phosphate (PI4-P). This means that recruitment of the 3D^{Pol} polymerase can be increased if

Figure 3 Formation of membrane tubes and double membrane vesicles by picornaviruses. (a) The picornaviruses polyprotein (i) encodes structural proteins (VP1–VP4) that generate the capsid and nonstructural proteins (2ABC and 3ABCD), required for replication. (ii) Processing of the polyprotein by 3C^{pro} generates the replicase from 2B, 2C, 2BC, 3A, and 3D^{pol} that are targeted to the cytoplasmic face of the endoplasmic reticulum by hydrophobic domains in 2B, 2C and 3A (iii). Replicase assembly leads to the generation of membrane tubes, the origins of the tubes are unknown but are likely to be derived from ER or cis Golgi. Later during infection tubes gain curvature, possibly powered by reticulon proteins (iv) and form double membrane vesicles (DMVs). (b) Electron micrograph of vesicles and tubes generated during coxsackievirus infection. The image is one of several tomographic slices used to generate rendered tomograms in panel C. Reproduced from Limpens, R.W., van der Scharr, H. M., Kumar, D., *et al.*, 2011. membranes contain increased levels of PI4-P. For some viruses this is achieved by manipulation of host proteins that control membrane traffic through the secretory pathway. The 3A protein of poliovirus and coxsackievirus increases the activity of the Arf1 GTPase and its guanine nucleotide exchange factor GBF1. Under normal circumstances activation of Arf1 by GBF1 results in formation of the COP1-coated vesicles that carry proteins

from the Golgi to the ER. Activation of GBF1 by the viral 3A protein, however, results in recruitment of an alternative Arf1 effector protein, phosphatidylinositol-4-kinase-III β (PI4-III β) to membranes (Hsu *et al.*, 2010). The enzyme phosphorylates PI4 to generate PIP-4 providing membranes enriched in PIP-4 which recruit 3D^{pol}. A similar mechanism may operate for flaviviruses (Reiss *et al.*, 2011; Berger *et al.*, 2009) and

coronaviruses (Verheije *et al.*, 2008) where replication and membrane remodeling are reduced following inhibition of the Arf1 GTPases or phosphatidylinositol-4-kinase-III.

(–) Strand RNA Viruses Replicate in Factories Assembled in the Golgi

The 'Bunyaviridae' are good examples of (–) strand RNA viruses and include Hantavirus, Rift Valley fever virus, and Crimean Congo hemorrhagic fever virus which cause severe diseases in man. The Bunyamwera virus serves as a good model for this family of viruses. The genome is segmented into three (–) strand RNA strands named according to their size. The long (L) segment encodes the RdRp, the medium segment encodes a polyprotein that is processed by the ER to make the envelope proteins Gn and Gc which travel to the Golgi apparatus, while the small segment encodes the nuclear protein (NP). One copy of each segment is packaged within the virus and each segment binds one copy of the RdRp and the rest of the RNA strand is protected by several NP proteins. On entering the cell the RdRp copies each (–) strand to make (+) strands that can be read as mRNA. Infection of cells with Bunyamwera virus results in the formation of tubules within the Golgi apparatus which form the virus factory (Fontana *et al.*, 2008). These tubules contain the RdRp, NP, and viral RNA. It is likely that they function as specialized spherules for generating new genome segments which are assembled with the RdRp and NP. The formation of the factory in the Golgi apparatus would facilitate delivery of RNA segments budding into late Golgi compartments during virus assembly and envelopment.

DNA Viruses

The Nucleo-Cytoplasmic Large DNA Viruses Use Aggresomes to Generate Pericentriolar Factories

The nucleo-cytoplasmic large DNA viruses (NCLDV) are a family of large DNA viruses with genomes ranging from 150 kb to 1.2 MB. The family includes the poxviruses iridoviruses, African swine fever virus (ASFV), phycodnaviruses, and mimiviruses that share several conserved core genes. The NCLDV infect a wide range of hosts including mammals, arthropods, fish, and marine plankton, but all replicate and assemble in large factories located close to the nucleus at the microtubule organizing center (MTOC) (Figure 4). The factories contain viral DNA and structural proteins but lack cellular membranes and are very similar to inclusions called aggresomes that form during protein misfolding diseases (Heath *et al.*, 2001; Wileman, 2007). Protein misfolding leads to the formation of small protein aggregates in the cytosol which are transported along microtubules by dynein motors to the MTOC where they encounter the major cellular pools of chaperones and proteasomes. If aggregates fail to fold, or exceed the proteolytic capacity of the proteasomes, they accumulate within an aggresome surrounded by mitochondria and a cage made from the vimentin filaments (Figure 4(a)). The inclusions also contain ubiquitin and a linker protein called p62/SQSTM1 that binds ubiquitin and LC3. LC3 is the major membrane protein of the autophagosome and p62 is used to remove ubiquitinated

Figure 4 Aggresomes and perinuclear sites generated by nucleocytoplasmic large DNA viruses. (a) (i) Misfolded proteins aggregate in the cytoplasm and bind to cytoplasmic dynein. (ii) Dynein motors move aggregated proteins by retrograde transport to the microtubule organizing center (MTOC). (iii) An aggresome forms and induces vimentin rearrangement and recruits of mitochondria and chaperones. (iv) Poxvirus cores enter the cytoplasm and bind dynein and microtubules and begin RNA replication. (v) Poxvirus cores are disassembled at the MTOC by proteasomes dynein and microtubules and begin DNA replication. (vi) DNA replication and virus assembly take place in factories located at the MTOC. (b) Virus factory generated by African swine fever virus. The image shows a vimentin cage (red) surrounding a virus factory containing newly assembled viruses (green). The nucleus is blue. (c) Electron micrograph African swine fever virus factory showing viruses at different stages of assembly. Fully assembled viruses are seen as hexagons in cross section. Those with dark centers have packaged DNA genomes.

proteins from aggresomes into autophagosomes which deliver them to lysosomes for degradation. Virus factories and aggresomes share many features in common including recruitment of chaperones, proteasomes, and mitochondria and confinement within a vimentin cage. Many viruses are recognized by dynein after entering cells and delivered to the MTOC. It is possible that incoming virus capsids stimulate an aggresome response because they appear foreign or misfolded to cells (Wileman, 2007). For the NCLDV this may be beneficial and provide transport to a site for replication, for other viruses it may represent an innate immune response leading to confinement at the MTOC and degradation.

The factories formed by poxviruses and ASFV are the best characterized. During cell entry the poxviruses release a viral core into the cytoplasm which binds dynein motor proteins (Figure 4(a)). The core immediately starts the synthesis of at least 100 early genes using a viral DNA-dependent RNA

polymerase. The mRNA transcribed from early genes by the polymerase are delivered into the cytosol as the core travels to the MTOC. The early proteins encoded by the mRNA are used to break open the core to release viral DNA through a process requiring proteasome-dependent degradation of ubiquitinated capsid proteins. Poxviruses are unusual DNA viruses because they encode all the enzymes needed for DNA and mRNA synthesis and do not need to travel to the nucleus. The viral genomes remain at the MTOC where they create a factory by providing a template for DNA replication and generation of viral mRNA encoding intermediate and late genes. Interestingly, for poxviruses it appears that intermediate and late proteins are synthesized within the factory rather than in the cytoplasm. This means that viral mRNA is retained within the factory and that the factory recruits cellular factors needed for translation. Detailed analysis of poxvirus factories shows that cavities within the viral DNA recruit viral mRNA, intermediate and late proteins, and host cell translation initiation factors such as eIF4g and eIF4e. The results suggest that translation of viral mRNA takes place on ribosomes recruited into the factory, and that sites of translation are segregated from sites of genome replication (Katsafanas and Moss, 2007). Viral structural proteins are retained in the factory until they are assembled into new viruses which are carried into the cytosol along microtubules.

Similar to poxviruses, infection of cells by ASFV also results in delivery of a nucleoprotein core particle into the cytosol. The cores deliver the genome to the nucleus where it provides a template for the formation of short precursor fragments that are exported to the cytosol for replication. The formation of the ASFV factory begins with the removal of cellular material from the MTOC where it is replaced by a high concentration of vimentin filaments arranged into an 'aster' aligned along microtubules. This site also recruits chaperones and mitochondria. Following the onset of DNA replication the vimentin filaments are rearranged into a cage surrounding virus DNA and delineate the edges of the factory (Figure 4(b)). The factory is kept at the MTOC by microtubules and becomes dispersed through the cytosol if microtubules are depolymerized. The rearrangement of vimentin into a cage requires phosphorylation of the N-terminal domain of vimentin that is important for filament assembly by host cell calcium calmodulin-dependent kinase II (CamKinase II). This phosphorylation is required for replication because inhibition of CamKinase II blocks late gene expression (Stefanovic *et al.*, 2005). In common with poxviruses, ASFV structural proteins do not leave the factory until they are assembled into new viruses (Figure 4(c)). At late stages in the lifetime of the factory the MTOC is lost and microtubules form bundles in the cytosol. It is thought that this may weaken the factory to facilitate release of viruses into the cytosol.

The DNA Viruses Generate Replication Compartments in the Nucleus

Most DNA viruses replicate in the nucleus because they need nuclear factors to generate new genomes (reviewed in Schmid *et al.*, 2014; Jiang and Imperiale, 2012). DNA viruses entering the cell are transported by dynein motors along microtubules to the MTOC where they are transferred to the nuclear pore complex for disassembly and release of the DNA genome into the nucleus (Figure 5). The viral genome must recruit host

Figure 5 Replication compartments generated by DNA viruses in the nucleus. (a) Herpes virus replication sites in the nucleus. DNA viruses are transferred from the MTOC to the nuclear pore complex for disassembly and release of the DNA genome into the nucleus. In many cases the RCs form close to the nuclear envelope next to a nuclear substructures called promyelocytic leukemia nuclear bodies (PML-NB) which vary between 100 and 1000 μm in diameter and contain PML Daxx, Sp100, and ATRX (i). PML-NBs have also been called nuclear aggresomes (ii) because they accumulate misfolded proteins, cellular chaperones, proteasome subunits, and ubiquitinated proteins. Viral DNA entering the nucleus lacks chromatin and exposes a damage signal that recruits PML-NB proteins to add chromatin to genomes and repress transcription (iii). For HSV-1 this cellular defense is countered by the regulatory protein ICP0 which targets PML for degradation (iv). The residue of the PML body (v) may form the 'assemblon' that is seen late during infection which contains tegument proteins and aggregated capsids. The assemblon may serve as a site of virus assembly early during infection and become the VICE domain/nuclear aggresome at later times when structural proteins are made in excess. Fully assembled capsids (vi) pass across the nuclear envelope and enter the cytoplasm and envelop in the trans-Golgi network before release from the cell. (b) Recruitment of PML-NB proteins to sites of HSV-1 replication. Cells were infected with a strain of virus (ΔICP0) lacking ICP0 to slow dispersal of PML-NB proteins. The fluorescence micrograph shows the virus genome located through detection of transcriptional activator ICP4 (green), PML protein (red) and DNA damage response protein γH2AX (blue). The PML protein has redistributed to sites containing viral DNA. Reproduced from Everett, R.D., 2013. The spatial organisation of DNA virus genomes in the nucleus. PLoS Pathogens 9, e1003386.

factors required for replication and establish sites for DNA replication and transcription in the nucleus, and at the same time evade cellular defenses against infection. The delivery of viral DNA to the nucleus initiates large-scale rearrangement of nuclear structures and the formation of replication compartments that can expand to fill the nucleus late during infection. In many cases the RCs form next to nuclear substructures called promyelocytic leukemia nuclear bodies (PML-NB), ND10s or PODs which store proteins involved in apoptosis, chromatin remodeling, and DNA repair (reviewed in [Everett, 2013](#); [Boutell and Everett, 2013](#)). Many of the components of the PML-NBs are upregulated by interferon suggesting they play a role in defense against infection. The RCs initially form close to the nuclear envelope, possibly where the viral DNA first enters the nucleus. A key question has centered on determining whether sites of DNA virus replication are indeed PML-NBs, and understanding how a virus would survive in a compartment designed to inhibit replication. The interaction of DNA viruses with PML-NBs is best studied for herpes simplex virus-1 (HSV-1), but is likely to be similar during the replication of other DNA viruses.

Use of promyelocytic leukemia nuclear bodies (PML-NB) by herpes virus

PML-NBs vary between 100 µm and 1000 µm in diameter and contain PML, the major structural protein, and Daxx, Sp100, and ATRX which regulate chromatin assembly and inhibit transcription. The PML-NBs do not move through the nucleus but PML proteins exchange rapidly with the surrounding nucleoplasm. Recruitment into the PML-NB is dependent on addition of ubiquitin-like SUMO proteins to PML, and the presence of SUMO interaction motifs in Daxx and Sp100. Viral DNA entering the nucleus lacks chromatin and this may expose a damage signal that recruits PML-NB proteins which would add chromatin to genomes and repress transcription ([Figure 5](#)). For HSV-1 this cellular defense is countered by the regulatory protein ICP0 which is expressed very early during infection. The ubiquitin E3 ligase activity of ICP0 ubiquitinates PML leading to degradation of PML by proteasomes and loss of PML-NBs from the nucleus of infected cells. Evidence that PML-NBs suppress virus replication before they are dispersed by ICP0 comes from the observation that HSV-1 strains expressing defective ICP0s fail to degrade PML, have reduced replication and can fail to proceed to lytic infection. Herpes viruses also use structural proteins to combat PML-NBs. The herpes virus nucleoprotein core is surrounded by a layer of tegument proteins (i.e., viral matrix) that lie beneath the envelope. The human cytomegalovirus tegument phosphoprotein pp71 locates to PML-NBs soon after cell entry and induces degradation of PML, similarly the major tegument protein of Epstein-Barr virus BNRF1 disassembles the Daxx-ATRX complex. Daxx-ATRX complexes are also displaced from PML-NBs by specific capsid proteins of adenoviruses and papillomaviruses that travel to the nucleus following cell entry.

PML-NBs have also been called nuclear aggresomes because they are closely associated with nuclear inclusions that accumulate misfolded proteins, cellular chaperones, proteasome subunits, and ubiquitinated proteins ([Fu et al., 2005](#)). Aggregated proteins, for example, the polyQ repeat proteins associated with Huntington's disease or spinocerebellar ataxia accumulate

close to, or within PML-NBs which fuse together to form larger structures. Nuclear aggresomes also appear during herpes virus infection, and in some reports they are called virus-induced-chaperone-enriched (VICE) domains. These domains appear adjacent to sites of replication soon after the dispersal of PML-NBs by ICP0. Proteomic analysis has shown that 20 or more host proteins may be recruited to replication sites. These include proteins involved in DNA replication and transcription, chromatin remodeling and DNA repair, and RNA polymerase II which is used to transcribe the viral genome. As seen for the poxviruses the sub-compartmentalization of the virus factory through the formation of a VICE domain may facilitate replication by sequestering structural proteins away from sites of genome replication and transcription. VICE domains may also store viral proteins, such as the UL6 viral portal protein, and pp65 tegument protein, that are prone to aggregation when they are made in excess over levels needed for the assembly of new viruses. Evidence that aggregation of viral proteins is detrimental to replication comes from studies of HCMV strains expressing a defective tegument protein called UL97. UL97 is a kinase that can reduce protein aggregation ([Prichard et al., 2005](#)). Drugs that inhibit the kinase activity of UL97, or mutations that abolish kinase activity, reduce replication and induce the formation of aggresomes containing tegument proteins.

Successful subversion of the cellular defenses provided by the PML-NB allows the virus to initiate DNA replication and transcription. Precisely where this occurs in the nucleus is not known because the PML-NB markers are dispersed by ICP0. The genomes of HSV-1 expressing a defective ICP0 accumulate in large PML-NBs making it likely that replication takes place within the residue of the PML-NB or VICE domain. Once genomes have been generated in the factory they have to be assembled with capsids. Capsid proteins are synthesized on ribosomes in the cytosol and imported into the nucleus where they assemble with scaffold proteins and a portal protein to generate empty immature capsids. Import of the genome through the portal results in proteolysis and loss of the scaffold and formation of the mature capsid. These events take place in the nucleus and early studies identified an 'assemblon' as a site of virus assembly, seen late during infection which contains tegument proteins and aggregated capsids. The assemblon may serve as a site of virus assembly early during infection and becomes the VICE domain/nuclear aggresome at later times when structural proteins are made in excess over levels that can be packaged into viruses. Fully assembled capsids pass across the nuclear envelope and enter the cytoplasm where they are enveloped in the trans-Golgi network before release from the cell.

Glossary

Acquired immunodeficiency syndrome Immunodeficiency disease caused by human immunodeficiency virus (HIV). Infection with HIV gradually damages the immune system, leading to increased susceptibility to infection by multiple opportunistic pathogens.

Lentiviruses Subgroup of retroviruses including HIV-1, HIV-2, and closely related simian immunodeficiency viruses.

Restriction factors Cellular proteins that inhibit viral replication.

Retroviruses Group of RNA viruses in which the RNA genome is reverse transcribed to DNA through the action of a virally encoded reverse transcriptase that is packaged into virus particles.

Reverse transcriptase Viral enzyme that converts RNA to DNA. Hallmark of retroviruses.

Virological synapse Intercellular contact across which viruses may be efficiently transferred from an infected to an uninfected cell.

Introduction

The human immunodeficiency virus type 1 (HIV-1) was discovered in the early 1980s in patients with so-called acquired immunodeficiency syndrome (AIDS). Subsequently, a compelling body of evidence has emerged that supports the hypothesis that HIV-1 infection in man is the primary cause of AIDS. Currently, about 35 million people worldwide are infected with HIV and a similar number have died as a consequence of the infection. Despite detailed knowledge of the mode of person-to-person transfer, new HIV infections continue at a rate of 2–3 million per year, mostly in sub-Saharan Africa.

HIV-1 is a lentivirus – a genus of the retrovirus family, i.e., it contains an RNA genome that is reverse transcribed into DNA following infection of new target cells. The virus is believed to have originated in great apes (chimpanzees and gorillas) by recombination of two coinfecting simian immunodeficiency viruses (SIV). SIV cpz/gor transferred to man on more than one occasion, but the main or M group HIV-1, which is the predominant group of viruses pathogenic in man, became established in the human population in the early twentieth century (Faria *et al.*, 2014). A second HIV, HIV-2, originating in West Africa, has also been described. This virus, derived from an SIV infecting sooty mangabeys (SIV smm), is genetically distinct from HIV-1, and less pathogenic in man. Here we will restrict our discussion to HIV-1.

HIV is mainly transmitted through sexual intercourse, but can also be transferred through transfusion of infected blood or blood products, through the use of contaminated needles, during child birth, and through breast-feeding. Following transfer, HIV targets the CD4-expressing (CD4⁺) subset of T lymphocytes and CD4⁺ myeloid cells (primarily macrophages and dendritic cells). By infecting cells of the immune system, HIV compromises the host's ability to mount effective immune responses, resulting in the pathology of AIDS.

Despite intense research, no HIV vaccine is currently available. However, progress has been made in understanding the cellular and molecular mechanisms involved in HIV

replication, and this work has led to the development of drugs that can reduce viral replication and limit the pathological consequences of infection. As with many viruses, HIV is genetically simple – its genome contains just nine open reading frames encoding 15 proteins (Figure 1(c)). Thus, virtually all aspects of the cell biology of HIV replication require that the virus interacts with and exploits host cell proteins and synthetic processes.

The HIV Replication Cycle

Overview

In its cell-free form HIV is a 130–140 nm diameter enveloped virus, i.e., virus particles are enwrapped by a bilayered lipid membrane, derived from the plasma membrane (PM) of infected cells, that protects the viral genome during the extracellular phase of the replication cycle (Figures 1(a) and 1(b), Figure 2). Virus entry into host cells is initiated by interaction of the viral envelope glycoprotein (Env) with specific cellular receptors (CD4 and a chemokine receptor, usually CCR5 and/or CXCR4), which determine the viral tropism for CD4⁺ cells (see Figure 2). Following Env-mediated membrane fusion, the viral RNA genome is reverse transcribed through the action of reverse transcriptase (RT), a virally encoded enzyme that is incorporated into virions during assembly. The reverse transcribed DNA is imported into the nucleus and integrated into specific sites of the host DNA. In some cases the integrated viral DNA (or provirus) can remain inactive or latent, but mostly it functions as a template for the synthesis of viral proteins and viral genomic RNA. New viral proteins either modify the functions of the infected cell, or are directed to the inner surface of the PM where, together with two copies of the viral genomic RNA, they assemble to form new virus particles.

HIV virions are formed from about 2500 copies of p55Gag, a 55 kDa polyprotein comprising the matrix (MA), capsid (CA), and nucleocapsid (NC) proteins (Figures 1 and 3(a)). About 150 copies of a second polyprotein – GagPol, the fused

Figure 1 Structure and genomic organization of HIV-1. (a) Transmission EM image of lentivirus particles (SIV) at the surface of a lymphocyte. Scale bar, 100 nm. (b) Diagram of the structure of a mature HIV particle, showing the location of the major viral proteins and the host cell-derived lipid envelope. (c) Organization of the HIV-1 genomic RNA (in black), indicating the 5' and 3' long terminal repeats (LTR), as well as the nine open reading frames that encode the viral polypeptides Gag, GagPol and Env, and the accessory proteins Vif (virion infectivity factor), Vpr, Vpu (viral proteins R and U, respectively), Tat (trans-activator of transcription), Rev (regulator of expression of virion proteins), and Nef (negative factor; note that these protein names are historical and do not always reflect a functional activity).

product of the Gag and Pol genes, bring the essential virally encoded enzymes protease (PR), RT, and integrase (IN) into forming virus particles. Additionally, multiple copies of the trimeric viral envelope protein (Env) are incorporated into each particle, as well as variable amounts of other viral proteins, including Vpr and Nef, a tRNA^{Lys3}, and other host cytosolic and membrane proteins. During or shortly after budding is completed, GagPol and p55Gag are cleaved by the viral PR to generate mature infectious HIV particles. This basic outline of the HIV replication cycle is illustrated in [Figure 2](#). The interactions of the virus with host cells will be described in more detail below.

Virus Assembly

Gag Coordinates HIV Assembly

HIV is assembled at the PM of infected cells. Although in T cells the virus buds from the cell surface, in monocyte-derived macrophages deeply invaginated intracellular domains

of the PM are the preferred sites for assembly and release. HIV assembly is driven by the main structural protein Gag ([Figure 3](#)) and, when expressed in cells, Gag alone can form noninfectious virus-like particles. Gag is a polyprotein synthesized from full-length transcripts of integrated proviral DNA (these transcripts also form the viral genomic RNA). A second *gag* product translated from the same mRNA is GagPol (or GagProPol). Gag and GagPol are both synthesized from the same initiation codon, but in about 5% of the translation reactions ribosomal frameshifting (the ribosome slips back one nucleotide and shifts from the *gag* reading frame to the *pol* reading frame) results in the synthesis of a fusion protein that contains the bulk of Gag as well as the viral enzymes encoded by the *pol* gene. This ensures that Gag is made in adequate amounts, but smaller amounts of the viral enzymes (PR, RT, and IN) are produced for incorporation into virus particles. Both Gag and GagPol are synthesized on cytoplasmic ribosomes, co-translationally myristoylated on the glycine residue at position 2 (after removal of the N-terminal methionine), and are assumed to be directed to the PM through similar mechanisms (see [Figure 3\(b\)](#)). Gag also

Figure 2 Cartoon illustrating the replication cycle of HIV. Left: HIV assembly. Viral genomic RNA and spliced mRNAs are produced by transcription from the integrated provirus and exported to the cytoplasm. Gag and GagPol polyproteins, as well as the HIV accessory proteins are synthesized on free ribosomes. Gag is targeted to the plasma membrane, where it oligomerizes, bending the membrane into a bud. The viral enzymes are incorporated into the bud by co-assembly with the GagPol polyprotein, and two copies of the viral genomic RNA are selected by the nucleocapsid portion of Gag. The Env protein is synthesized on the rough endoplasmic reticulum and transported to the plasma membrane via the Golgi/TGN. Immature virus particles are released from the plasma membrane by ESCRT-mediated scission of the bud stalk. Concomitant with or shortly after scission, the viral protease, PR, cleaves Gag and GagPol polyproteins, allowing the rearrangements that result in the formation of the characteristic cone-shaped cores of mature infectious viruses. Right: HIV entry. HIV binds its target cells via CD4 and a chemokine co-receptor, CCR5 or CXCR4, and fuses with the target cell plasma membrane, or from within an endosome after endocytosis of the virus. Following fusion, the RNA genome is reverse transcribed into DNA complex and transported into the nucleus – though the exact details of these steps are still poorly understood. In the nucleus, the viral integrase incorporates the DNA provirus into the host genome, where it may remain inactive (in a latently infected cell), or serve as a template for new viral RNAs.

recruits viral genomic RNA to the PM. The NC domain of Gag has two zinc fingers that select two copies of HIV RNA for packaging via the conserved ψ motif (Figure 3(d)).

Gag oligomerization is initiated in the cytoplasm and involves interaction with a number of cellular proteins, but the significance of most of these interactions for targeting Gag to the PM, and for virus assembly, remains unclear (Giese and Marsh, 2013). The ABCe1 ATPase complex, for example, has been proposed to function as a chaperone for newly synthesized Gag (Zimmerman *et al.*, 2002), and several reports have suggested that microtubule motor proteins play roles in Gag transport (Brass *et al.*, 2008; Azevedo *et al.*, 2009). In addition, the cellular lipid phosphatidylinositol-4,5-bisphosphate [PI(4,5)P₂] is particularly important for HIV assembly. PI(4,5)P₂ is located mainly in the inner leaflet of the PM, where it functions

in targeting many cytosolic proteins to the PM. When cellular PI(4,5)P₂ is depleted, by over-expression of PI 5-phosphatase IV, Gag is redirected to late endosomes, and virus production is impaired. Similarly, over-expression of a constitutively active Arf6 leads to the formation of intracellular vesicles rich in PI(4,5)P₂, and redirects HIV assembly to these internal vesicles (Ono *et al.*, 2004).

Gag is targeted to the cytoplasmic leaflet of the PM via its N-terminal MA domain, which is myristoylated; membrane association is further stabilized by a basic region on the surface of MA (residues 16–31) (Figure 3(b)). Gag molecules containing mutations that prevent myristoylation, or that disrupt the basic patch, are mis-targeted and fail to support budding (Sundquist and Kräusslich, 2012). The myristoylation, as well as binding of MA to PI(4,5)P₂, direct Gag to so-called lipid

Figure 3 Cartoon illustrating the multiple functions of Gag in coordinating virus assembly. (a) Diagram of the HIV-1 Gag polyprotein, showing the N-terminal myristic acid moiety and the protein components Matrix (MA or p17), Capsid (CA or p24), Nucleocapsid (NC or p7) and the p6 domain, as well as the spacer peptides SP1 and SP2. Arrows indicate cleavage sites for the HIV-1 protease, PR. (b) The 'Matrix (MA)' domain targets the Gag polyprotein to the plasma membrane. MA binds to the plasma membrane via the N-terminal myristate and a highly basic region (indicated in blue). Membrane association is further stabilized by binding to the phospholipid PI(4,5)P₂ when the 2' acyl chain of PI(4,5)P₂ is extracted from the membrane and binds into a hydrophobic groove or channel in MA. The membrane-associated MA is organized into trimers (shown in the diagram on the right, orthogonal view to the membrane), which are loosely arranged into a hexameric lattice. (c) Role of the 'Capsid (CA)' in Gag oligomerization. CA can associate into at least two distinct hexameric configurations. As part of the Gag polyprotein in immature particles (left hand side), CA forms a lattice of hexamers of about 8 nm periodicity with occasional faults and gaps, allowing the formation of a spherical bud. After cleavage by PR and maturation of the viral core, CA reassembles into a distinct hexameric configuration (periodicity of about 9.5 nm, right hand side). The HIV core consists of about 250 CA hexagons and 12 pentagons to allow curvature (5 at the narrow and 7 at the blunt end). The CA N-terminal domain (NTD) and C-terminal domain (CTD) are indicated by dark and lighter orange shading, respectively. (d) The 'Nucleocapsid (NC)' of Gag contains two zinc finger domains that bind to the HIV genomic RNA via the ~150 nucleotide packaging sequence, Ψ. Two copies of the genomic RNA are incorporated into each virus particle. (e) The C-terminal 'p6' domain of Gag contains consensus sequences for binding of the ESCRT-I component Tsg101. In addition, p6 is able to bind the ESCRT-associated protein AIP1/ALIX that can recruit ESCRT-III or ESCRT-I to the assembling virion. p6 is also required for incorporation of the viral protein r (Vpr).

rafts, and HIV budding has been suggested to occur mainly through these liquid-ordered domains. Disruption of raft domains has been shown to reduce HIV release (Ono and Freed, 2001), and virus budding through raft domains may also explain why the membranes of HIV particles appear enriched for sphingolipids and cholesterol.

Following recruitment to the cytoplasmic leaflet of the PM, Gag assembles into a hexameric lattice that drives the formation of a membrane bud (Figure 3(c)). High-resolution cryo-electron tomography of immature particles shows the interactions between the CA domains of Gag that are crucial for lattice formation and virus particle assembly (Sundquist and Kräusslich, 2012).

Envelope Glycoprotein (Env) Trafficking

HIV Env is a type I integral membrane protein that must also be transported to the sites of virus assembly to be incorporated into nascent particles. Env is synthesized on the endoplasmic reticulum (ER) as a 160 kDa precursor, and in infected cells the bulk of the protein is located in the ER lumen. Gp160 trimerizes in the ER and is extensively glycosylated at up to 30 N-linked glycosylation motifs. Subsequently, the trimeric glycoprotein is transported to the Golgi apparatus, and eventually the PM. During transit through the secretory pathway some, but not all, of the N-linked oligosaccharides are processed to complex forms, and gp160 is cleaved by cellular furin or furin-like proteases to form the mature, non-covalently linked subunits, the surface unit (SU, or gp120) and the transmembrane protein (TM, gp41) (Figure 4). This proteolytic cleavage unmasks the hydrophobic fusion peptide at the new N-terminus of gp41, rendering Env competent for membrane fusion (Figure 5; Merk and Subramaniam, 2013). Currently, it remains unclear how exactly Env trimers are recruited into budding virions. However, EM tomography indicates that the number of Env trimers incorporated is low, with estimates ranging from 4 to 30 per virion (Zhu *et al.*, 2006).

The gp41 C-terminal cytoplasmic domain consists of about 150 amino acids and contains several conserved short sequence motifs homologous to trafficking signals of cellular proteins. The best characterized of these are a membrane-proximal GYxxØ motif and a C-terminal di-leucine motif (Figure 4). Both of these signals mediate AP-2 binding and clathrin-dependent endocytosis, and therefore regulate the distribution of Env in infected cells. Internalized Env is delivered to early endosomes, and can subsequently return to the PM via recycling endosomes. However, some Env is also sorted to late endosomes and lysosomes, where it is degraded. As a result, the steady state levels of Env on the surface of infected cells are low, which is likely to contribute to the low levels of Env incorporated into virions (Giese and Marsh, 2013).

HIV Release and Maturation

Live cell fluorescence imaging experiments indicate that it takes 5–10 min from the first appearance of Gag at the PM to complete recruitment of HIV components, though another 16–17 min may pass before the particles detach from the cells (Jouvenet *et al.*, 2008). Virus release requires that the narrow stalks, which connect budded particles to the PM, are cut

Figure 4 Cartoon showing the organization of the HIV-1 envelope glycoprotein (Env). HIV Env is a trimer of hetero-dimers comprising the surface glycoprotein SU (gp120, in light green) and the transmembrane protein TM (gp41, in gray). About half of the mass of gp120 consists of N-linked glycan residues, both complex as well as high mannose glycans, which shield the protein from antibody binding. The location of the V1V2 and V3 variable loops and the CD4 binding pocket are indicated. Other important neutralizing antibody epitopes are found at the crown of gp120 and in gp41 (the membrane-proximal external region, MPER). The locations of the conserved endocytosis signals in gp41 (GYxxØ and di-leucine) are also indicated.

by the endosomal sorting complex required for transport (ESCRT) machinery. A number of enveloped viruses use the cellular ESCRT complexes to allow their release from cells, and each has evolved one or more short amino acid sequences to mediate ESCRT recruitment. For HIV and related viruses, the C-terminal p6 domain of Gag (also termed the 'late domain' due to its requirement late in the assembly pathway) contains a PTAP motif that mimics the PSAP sequence in the ESCRT-0 protein Hrs that is responsible for recruiting the Tsg101 component of ESCRT-I to endosomes (Figure 3(e)). This PTAP-Tsg101 interaction is the main mechanism of ESCRT recruitment during HIV assembly, and mutations in the PTAP motif arrest virus budding at a late stage. The HIV Gag p6 domain also contains a second late domain motif, LYPx(n)L, which binds the ESCRT-associated protein AIP1/ALIX that can recruit both ESCRT-I and ESCRT-III. In the absence of a functional PTAP motif, over-expression of ALIX can partially rescue HIV release, though the affinity of ALIX for the LYPx(n)L motif is low, and thus it may not be able to rescue the release of PTAP mutants at physiological concentrations (Fisher *et al.*, 2007). The mechanism of ESCRT-mediated membrane scission is currently a major focus for research, with complementary views on how the machinery is assembled to

mediate membrane fission in the context of a budding virus (Sundquist and Kräusslich, 2012).

During, or shortly after virus release, autocatalytic activation of the viral PR leads to processing of both Gag and GagPol to generate the proteins of the mature virus. CA is reassembled around the viral RNA, NC, RT, and IN to form the conical capsid structure seen in mature viruses. As in immature particles, CA forms a hexagonal lattice, but with different contacts between the CA subunits (see Figure 3(c)). The inclusion of 12 pentameric units within the lattice allows for the formation of a closed capsid structure (Sundquist and Kräusslich, 2012). These distinct arrangements of the Gag CA domain in immature and mature virions drive two complementary processes in the HIV replication cycle, namely initial particle assembly and the formation of the mature capsid, which is essential for the subsequent activities of the virus core post fusion. The transition between the conformations is dependent on PR-mediated cleavage of Gag, thereby ensuring that these steps take place in the correct temporal sequence.

Virus Transmission

Following release from infected cells, viruses can spread by passive diffusion through extracellular fluids to infect receptor-positive cells. Most, if not all, viruses can use this cell-free mode of transmission. However, in many cases viruses may also spread by cell–cell transmission, during which an infected and a target cell come into direct contact. HIV has been suggested to exploit various structures for its direct cell–cell spread, of which the virological synapse (VS) is currently the best characterized, and is likely to be the most efficient. VS are named for their structural similarities to immune synapses, and are characterized by an accumulation of HIV proteins and the cellular receptors CD4 and CCR5/CXCR4 at intercellular junctions between infected and target cells. The high local concentrations of both infectious particles and their receptors are thought to promote efficient virus transfer (Sattentau, 2010).

Since there is no need for virus particles to diffuse over long distances, cell–cell transmission is likely to be faster than cell-free spread. As a consequence, viruses may be less likely to be detected by the immune system, and in some cases the intercellular contacts exploited for transmission may shield viruses from neutralizing antibodies (Sattentau, 2010).

In tissue culture, HIV exploits both cell-free and cell–cell transmission for its propagation, but the relative contributions of the two processes to virus spread *in vivo* remain unclear. In HIV-infected individuals, replication is observed in areas that are densely populated by migratory cells, e.g., gut-associated lymphoid tissue and peripheral lymph nodes, which would provide an ideal environment for direct cell–cell spread. Moreover, the observation of local ‘hotspots,’ or foci, of HIV replication in the tissues of HIV patients suggests that direct cell–cell propagation does occur *in vivo*. Recently, intravital multiphoton microscopy has revealed that HIV-infected T cells form stable contacts with uninfected CD4⁺ cells in the lymph nodes of humanized mice, but whether these contacts lead to the transfer of virus and infection of target cells remains unclear (Murooka *et al.*, 2012).

Virus Entry

Receptor Dependence and Specificity – Site of Fusion

HIV enters cells by fusion of its envelope with a target cell (Figure 5). Membrane fusion requires binding of the gp120 subunit of Env to its cellular receptor CD4 and to a chemokine co-receptor, mainly CCR5 and/or CXCR4. Most viruses use CCR5, but CXCR4-tropic viruses emerge in ~50% of patients at late stages of infection. Initial binding to CD4 triggers conformational changes in gp120, which reveal the co-receptor binding site, a bridging sheet at the base of the so-called gp120 V3 loop (see Figures 5(b) and 5(c)). Co-receptor binding triggers further conformational changes that result in major changes in the conformation of gp41. As a result, the gp41 N-terminal fusion peptide inserts into the target cell membrane (Figure 5(d)), and the subsequent refolding of the ectodomain of the trimeric gp41 to form a stable six-helix bundle (Figure 5(e)) is thought to bring the viral and cellular membranes into close apposition (Figure 5(f)) and trigger fusion of the viral and target membranes (Figure 5(g)). HIV is generally assumed to fuse with the PM of target cells, but some reports indicate that fusion may occur in endosomal compartments, particularly following the direct cell–cell transfer of viruses (Melikyan, 2014). Although HIV fusion is triggered by receptor engagement and not pH changes, the mechanism is likely to be similar to that of other viruses with type I fusion proteins, in particular influenza viruses.

Reverse Transcription

Regardless of where fusion occurs, it releases the HIV core into the cytoplasm of the target cell where reverse transcription and uncoating take place (see Figure 2). The temporal order and subcellular localization of reverse transcription and uncoating remain controversial (Hilditch and Towers, 2014). Recent evidence suggests that reverse transcription is initiated before significant uncoating occurs, though both processes may proceed in parallel. The resulting nucleic acid/protein complexes are referred to as reverse transcription complex (RTC), and subsequently the pre-integration complex (PIC), but the precise composition of the RTC and PIC remain elusive. For example, some studies suggest that most CA is lost during uncoating, but other researchers have reported functions for CA in nuclear import and even in the chromosomal integration of HIV DNA, suggesting that at least some CA remains associated with the RTC/PIC (Fassati, 2012).

Reverse transcription of the viral RNA genome takes place in the RTC. It is primed by a single molecule of tRNA^{Lys3} bound to the primer binding site of the viral RNA. RT mediates RNA-dependent DNA transcription of the positive-sense RNA genome, digestion of the transcribed RNA, and DNA-dependent DNA polymerization to produce double-stranded HIV DNA. HIV RT lacks proof-reading capacity, resulting in an error rate of 3×10^{-5} /nucleotide/replication cycle. Thus, reverse transcription is responsible for the high mutation rate seen in HIV, which in part leads to its genetic diversity (the nucleotide sequence of HIV Env differs by 20–30% between isolates and by up to 10% between viruses from one individual). In addition, recombination between different HIV

Figure 5 Cartoon showing the HIV envelope-induced membrane fusion process. The components of the fusion reaction shown in (a) comprise the Env trimers in the viral membrane, and the HIV receptor CD4 and a chemokine receptor (usually CCR5 or CXCR4) in the target cell membrane. Binding to CD4 (b) leads to conformational changes in Env that then allow binding to the co-receptor (c). This leads to further conformational rearrangements, with gp120 opening out and allowing the fusion peptide at the N-terminus of gp41 to insert into the target cell membrane (d). The extended conformation of gp41 is inherently unstable and the protein folds back on itself into a hairpin structure (the 6-helix bundle), pulling the viral and target cell membranes into close apposition (e) and leading to the formation of the metastable hemi-fusion intermediate (f) and full fusion of the viral and cell membranes (g).

genomes can occur when cells are simultaneously infected with several virions. The plethora of antigenically distinct HIV quasi-species found within HIV-infected individuals presents a challenge to the immune system, which consequently is unable to mount an effective response to the infection.

Nuclear Entry and Integration

Following reverse transcription, double-stranded genomic HIV DNA, associated with the PIC, is delivered into the nucleus of cells. In contrast to other retroviruses, HIV can infect post-mitotic as well as dividing cells. Therefore, the virus must be able to deliver its genome across the intact nuclear envelope, presumably through nuclear pore complexes. Nuclear localization signals in several PIC-associated viral proteins have been suggested to mediate nuclear import, but the extent to which any of these proteins is involved is unclear. The ability of HIV to infect nondividing cells makes HIV-1-based lentiviral vectors particularly useful for gene transfer.

Once inside the nucleus, HIV DNA is integrated into the host cell genome. The viral IN clips several nucleotides at the 3' ends of the double-stranded HIV DNA, cleaves the host cell chromosome, and joins the 3' ends of the viral and cellular DNA. Remaining gaps are filled by cellular DNA repair enzymes.

Integrated HIV DNA can serve as a template for the production of mRNA and the synthesis of viral proteins, but in some cells it is not transcribed, and the infected cells remain in a latent state. Latency represents a major obstacle to the cure of HIV, as cells that do not synthesize viral proteins are resistant to drugs and host immune defenses. The mechanisms by which latent HIV is reactivated currently remain unknown.

Synthesis of New Viral Components

In productively infected cells, integrated proviral HIV DNA is transcribed by the cellular RNA polymerase II. Transcription is initiated at the 5' long terminal repeat (LTR), and promoted by a TATA box located approximately 25 base pairs (bp) upstream of the transcription start site. Subsequently, the viral accessory protein Tat binds to the trans-activation response element (TAR) of the nascent mRNA molecule, recruits the human positive-transcriptional elongation factor b (P-TEF-b), and thereby further enhances transcription. Gag and GagPol are translated from unspliced HIV mRNA, whereas Env, Vif, Vpr, and Vpr are synthesized from partially spliced RNAs. Although unspliced and partially spliced mRNAs are normally retained in the nucleus, HIV uses the accessory protein Rev to overcome this barrier to replication. Rev, as well as the accessory proteins Tat and Nef, is translated from fully spliced mRNAs early in infection. Multiple copies of Rev bind to a Rev responsive element (RRE), which is located in the Env coding sequence of all unspliced or partially spliced mRNAs, and interact with the nuclear export factor CRM1 to transport unspliced and partially spliced HIV RNAs into the cytoplasm. In addition to its function as a template for the translation of Gag and GagPol, unspliced viral mRNA also forms the genomic RNA that is incorporated into infectious particles.

Cell Killing

HIV infection culminates in the depletion of CD4⁺ T cells, one of the defining characteristics of AIDS. However, numerous studies have shown that the death of infected cells alone cannot account for the rapid progression and extent of T cell depletion in patients. Moreover, HIV-infection also leads to a loss of CD4-negative (CD4⁻) cells, including B cells and neurons. These observations indicate that HIV kills both infected, as well as uninfected 'bystander' cells, though many of the underlying mechanisms remain controversial.

HIV-infected cells can die from direct consequences of virus replication, or from cytotoxicity mediated by other immune cells. A direct consequence of HIV replication is the integration of viral DNA into the host cell genome. In activated CD4⁺ T cells, this step of virus replication may trigger a cellular DNA damage response and culminate in cell death by apoptosis (Cooper *et al.*, 2013). The accumulation of HIV RNA and proteins in infected cells may also cause cytotoxicity.

Cytotoxic T lymphocytes (CTL) induce apoptotic cell death in HIV-infected cells that present MHC-I-associated viral peptides at their surface. To avoid CTL killing, many viruses down-regulate MHC-I molecules. However, cells that do not present MHC-I at their surface are in turn targeted by NK cells. To circumvent both the CTL and NK cell immune defense mechanisms, HIV only down-modulates subsets of MHC-I molecules (Cohen *et al.*, 1999).

NK cells, macrophages and neutrophils express Fc receptors at their surface, which enables them to recognize and kill antibody-coated HIV-infected cells in a process called antibody-dependent cellular cytotoxicity (ADCC). ADCC depends on the presence of HIV-specific antibodies, which bind to cell surface Env on infected cells, or to Env proteins incorporated into cell-associated virus particles, and recruit the cytotoxic immune cells via their constant antibody regions (Fc regions).

The depletion of uninfected bystander cells in HIV-infected patients is mainly attributed to the induction of apoptosis. HIV induces a state of chronic immune activation, which is characterized by an upregulation of genes of the TNF family, including the pro-apoptotic receptors Fas and TRAIL (Poonia *et al.*, 2009). Moreover, abortive infection of quiescent CD4⁺ T cells has been suggested to result in intracellular accumulation of unintegrated viral DNA, which may be detected by a cellular DNA sensor and lead to cell death by pyroptosis (Monroe *et al.*, 2014). The interplay of these multiple cell killing mechanisms can explain the rapid loss of CD4⁺ as well as CD4⁻ cells during HIV infection, and can account for diverse symptoms associated with AIDS.

Host Defences against HIV

Humoral and Cellular Immunity

The evolutionary pressure imposed by viruses and other pathogens has given rise to immune defences that counteract viral replication. *In vivo*, HIV infection triggers both innate and adaptive immune responses, which are further subdivided into cellular and humoral immunity.

Macrophages and dendritic cells are mediators of the innate cellular defense. As professional antigen presenting cells (APC), these cells phagocytose HIV-infected cells, present foreign antigen to other immune cells, and secrete pro-inflammatory cytokines that attract cells of the adaptive immune response. Following their recruitment, B and T cells are activated by APCs. B cells mature and secrete specific antibodies, which are the main mediators of the humoral immune response. However, due to the viral immune evasion strategies described above, antibodies are unable to control HIV infection *in vivo*. CTL recognize and eliminate cells that present MHC-I-associated HIV antigens on their surface. These cells appear to more efficiently counteract HIV, and are assumed to mediate the temporary drop in viral load following the acute phase of infection but ultimately also fail to clear infected individuals of HIV.

Restriction Factors

In addition to cellular and humoral immunity, protective responses to viral pathogens can involve cellular proteins that directly counteract virus replication within infected cells. These so-called restriction factors have a number of common characteristics: (1) Their expression is usually enhanced, or induced, by type I interferons (IFN), which are upregulated following infection with intracellular pathogens such as viruses. (2) They directly inhibit viral replication, rather than mediating their effects through activation of a broad and nonspecific immune response, though some restriction factors function as pattern recognition receptors and activate inflammatory cellular signaling pathways in addition to their direct effects on viral replication. (3) Since restriction factors can present major barriers to viral replication, successful viruses often encode antagonists that operate via direct protein-protein interactions. (4) Mutations in the restriction factors that abolish their interactions with the viral antagonists offer an advantage to the host, and are thus selected for during evolution. Viruses in turn adapt their antagonists to maintain activity against the modified restriction factors. As a result, restriction factors show signatures of rapid evolution. HIV replication is inhibited by a number of restriction factors, including TRIM5 α , SAMHD1, APOBEC3G, and Tetherin (Figure 6; Malim and Bieniasz, 2012).

TRIM5 α

TRIM5 α is an E3 ubiquitin ligase that acts on HIV-1 early in the replication cycle. It assembles into a lattice surrounding the incoming capsid, and is thought to disassemble the viral core before reverse transcription can occur. Ubiquitin ligase activity is necessary for its antiviral activity, and during restriction TRIM5 α is auto-ubiquitinated and ultimately degraded via proteasomes. TRIM5 α may also inhibit replication after reverse transcription, and has recently been shown to activate the NF κ B pathway to promote the expression of pro-inflammatory cytokines.

SAMHD1

SAMHD1 is an IFN-inducible restriction factor that has been suggested to interfere with HIV reverse transcription by

depleting cellular dNTP pools, though other mechanisms may exist. Although HIV-2 and SIV from macaques (SIV mac) can antagonize SAMHD1 through their Vpx protein, HIV-1 does not encode a Vpx analog and is unable to antagonize SAMHD1.

APOBEC3G

APOBEC3G also targets HIV reverse transcription, but it does so through a mechanism that is distinct to that employed by SAMHD1. APOBEC3G is a cytidine deaminase that catalyzes cytidine-to-uridine hypermutations during reverse transcription. Cytidine-to-uridine mutations in the negative-strand lead to guanine-to-adenine mutations in the proviral DNA. Thus, HIV DNA isolated from AIDS patients shows high levels of guanine-to-adenine changes. These mutations frequently lead to premature stop codons or amino acid changes that prevent subsequent steps of HIV replication. APOBEC3G has also been suggested to inhibit reverse transcription and integration by mechanisms independent of its deaminase activity. In virus-producing cells, APOBEC3G is packaged into HIV particles via RNA-dependent interactions with the NC domain of Gag, but it exerts its effects in newly infected cells. The HIV accessory protein Vif, together with the cellular co-factor CBF β , antagonizes APOBEC3G by recruiting the E3 ubiquitin ligase complex elongin B/elongin C/RBX/Cullin5, which mediates APOBEC3G ubiquitination and proteasomal degradation.

Tetherin

Tetherin (or Bst-2, HM1.24, CD317) impedes HIV replication late in the virus replication cycle. The 20 kDa glycoprotein has an unusual topology, in that it has both an N-terminal transmembrane domain and a C-terminal glycosylphosphatidylinositol (GPI) anchor. During virus assembly, one end of the dimeric protein (predominantly the C-terminus) is incorporated into budding particles, while the other remains inserted in the host cell PM. Consequently, fully formed HIV particles remain tethered to infected cells, and are subsequently internalized and targeted for lysosomal degradation. Tetherin may also inhibit HIV replication by activating the pro-inflammatory NF κ B signaling pathway. Since Tetherin targets the viral membrane, an immutable structure inherent to all enveloped viruses, many viruses that assemble at the PM are susceptible to Tetherin restriction. Indeed, Tetherin has been shown to restrict all tested retroviruses, the filoviruses Ebola and Marburg, the arenaviruses Lassa and Machupo, the paramyxoviruses Sendai and Nipah, the rhabdovirus vesicular stomatitis virus, as well as the herpes viruses HSV-1 and Kaposi's sarcoma-associated herpesvirus, which gain their membranes on intracellular compartments. Most, if not all, inhibited viruses encode proteins that antagonise Tetherin. In HIV-1 this is done by the accessory protein Vpu, which interacts with Tetherin and promotes its lysosomal degradation (Neil, 2013).

Drugs Interfering with HIV Replication

HIV relies on cellular processes throughout its replication cycle. However, some steps of replication are dependent on virally encoded proteins, and interfering with these can limit

Figure 6 Cartoon illustrating points in the HIV replication cycle where restriction factors or antiretroviral drugs exert their effects. Diagram of the HIV replication cycle (see [Figure 1](#)). The site of action of four restriction factors, TRIM5 α , SAMHD1, APOBEC3G and Tetherin, are indicated in dark red. TRIM5 α acts on the incoming HIV core and interferes with the uncoating steps, SAMHD1 has been suggested to deplete the cellular dNTP pools required for reverse transcription, and APOBEC3G induces mutations in the viral DNA (indicated as stars). Tetherin retains budded virus particles on the surface of infected cells and leads to their internalization and degradation. The sites of action of various classes of antiretroviral drugs are indicated in purple, with selected examples. NNRTI non-nucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor.

replication without disrupting essential cellular processes. A number of antiretroviral drugs are now available that target these virus-specific steps. These include viral entry, reverse transcription, DNA integration, and maturation (protease) inhibitors ([Figure 6](#)).

RT inhibitors were the first anti-HIV drugs to receive approval by the US Food and Drug Administration (FDA). They are subdivided into two classes: nucleoside reverse transcriptase inhibitors (NRTI) and non-nucleoside reverse transcriptase inhibitors (NNRTI). NRTI consist of synthetic nucleoside analogs, which lack the 3'-OH group necessary for transcriptional elongation. When incorporated into the growing viral DNA, they terminate reverse transcription. NNRTI bind to RT outside the nucleotide binding site, induce conformational changes, and thereby inhibit RT activity. With currently 13 and six FDA-approved NRTI and NNRTI, respectively, RT inhibitors are the most abundant anti-HIV drugs.

Any of these drugs potentially inhibit HIV replication *in vitro*. However, when administered singly to patients, drug-resistant strains rapidly emerge due to the high mutation rate of the

virus. To limit the emergence of drug resistance, highly active antiretroviral therapy (HAART) nowadays consists of a combination of up to four antiretroviral drugs. Though this therapy can decrease the viral load to undetectable levels and prevent progression to AIDS, adverse effects are frequent and may negatively impact on patient compliance. Significantly, HIV usually reappears rapidly if HAART is stopped due to its ability to exist in latent form within subpopulations of CD4⁺ T cells and in other reservoirs such as macrophages.

Conclusion

Since its discovery in the early 1980s, HIV has become one of the best characterized viruses. Many aspects of its evolution, structure, mode of replication, interaction with its human host and mechanisms of pathogenesis are understood in detail. Nevertheless, and despite its relative genetic simplicity, there is much that remains to be understood. In particular, full understanding of how HIV evades cellular defenses, how the virus is assembled and transmitted within infected individuals,

and whether it is possible to develop effective immunological antiviral protection remain major challenges. Increasing our understanding of how HIV and related viruses engage with target cells, and elucidating the spectrum of molecular interactions involved in these engagements, will continue to be areas of active research for the foreseeable future.

Introduction

Prion diseases, or transmissible spongiform encephalopathies (TSEs), are a group of closely related, unfailingly fatal neurodegenerative disorders characterized by motor and cognitive impairments, extensive brain damage, and neuronal dysfunction. These diseases include Creutzfeldt–Jakob disease (CJD), Gerstmann–Sträussler–Scheinker syndrome (GSS), fatal familial insomnia (FFI), and kuru in humans; scrapie in sheep and goats; bovine spongiform encephalopathy (BSE) in cattle; and chronic wasting disease (CWD) in cervids.

Stanley B. Prusiner first proposed the then heretic idea that the infectious pathogen responsible for these diseases could be transmitted and propagated without the need for nucleic acids but rather with protein forming the essential pathogenic component. He referred to this idea as the ‘protein-only’ hypothesis. He also proposed the term ‘prion’ to define this unusual proteinaceous infectious agent that causes prion diseases. The prion, denoted PrP^{Sc} for scrapie prion protein (PrP), is the abnormal, disease-causing form of the physiologically expressed cellular prion protein, PrP^C.

History of the Prion Discovery

Scrapie, a naturally occurring prion disease affecting sheep and goats has been recognized in Europe for more than 250 years (McGowan, 1922). The name scrapie originates from a clinical sign of the disease, as afflicted animals will compulsively scrape off their fleeces against objects. Scrapie was shown to be transmissible by inoculation between sheep (Cuille and Chelle, 1936). Much later, the scrapie agent of sheep was successfully transmitted to mice and rats (Chandler, 1961; Chandler and Fisher, 1963).

In the 1950s, there arose an epidemic of a neurodegenerative disease among the indigenous Fore population of Papua New Guinea. This neurodegenerative disease, known as kuru, was characterized by progressive ataxia and was thought to be linked to symbolic cannibalistic activities practiced among the people. It was recognized that kuru (and later CJD) histopathologically resembled scrapie. This led to the idea that these diseases were somehow related and they too may be transmitted by intracerebral inoculation (Klatzo *et al.*, 1959). This was shown with two seminal experiments wherein brain homogenates from diseased humans were inoculated into chimpanzees, resulting in disease in the chimpanzees which mimicked the human diseases (Gajdusek *et al.*, 1966).

This work showed that the neurodegenerative diseases kuru and CJD (and later work showed that FFI and GSS also) were transmissible. Still unclear was the nature of the transmissible agent. Although many initially thought a ‘slow virus’ was responsible, this was challenged by the failure to convincingly demonstrate such a virus, lack of an immunological response by the body to infection and especially by evidence presented

by Alper *et al.* (1967) suggesting that the transmissible agent was resistant to treatments known to inactivate nucleic acid.

Building on Alper’s work, Griffith was the first to propose a model illustrating that the scrapie agent could be a protein devoid of nucleic acids (Griffith, 1967). This idea was based on the strong experimental evidence that no conventional pathogen could resist such high doses of ionizing or UV radiation, but a polypeptide could. The model challenged the central dogma of biology by suggesting that proteins, and not exclusively DNA or RNA, could store and propagate biological information.

The protein-only model was quite ahead of its time, and it was not until 1982 that Stanley B. Prusiner worked to forward Griffith’s model. Prusiner collected all the evidence amassed thus far and argued that since several procedures that inactivate nucleic acids would not prevent scrapie infectivity, the agent must be a protein. He coined the term ‘prion’ defined as ‘small proteinaceous infectious particles that resist inactivation by procedures which modify nucleic acids’ and thereby clearly distinguishing the infectious pathogen from viruses or viroids (Prusiner, 1982). Prusiner and colleagues found that a novel protein in the brains of animals inoculated with the scrapie agent was the major component of infective materials (Bolton *et al.*, 1982).

Soon after, this novel infectious protein was found to be encoded within the host’s own genome and named PrP (Oesch *et al.*, 1985). The discovery that the infectious agent of scrapie was a host-encoded protein helped to explain why the body had no immunological response to the disease and how nucleic acids were not needed for the disease’s propagation, but still unclear was how PrP could cause disease. Evidence from biophysical studies indicated that PrP associated with disease possessed a different folding pattern, or tertiary structure, than the physiological PrP present in most mammalian cells. This has led to the concept that the change of PrP structure can impart the characteristics of an infectious agent. Researchers today are still struggling to fully understand how a misfolded protein is able to cause disease.

Despite all of the evidence put forward, there still lingered doubts. To dispel such doubts the Prusiner group developed infectious prions outside of mammalian cells via recombinant proteins produced in bacteria. These synthetic mammalian prions caused disease in animal models, providing the final evidence of the prion puzzle (Legname *et al.*, 2004).

In 1997 Prusiner was awarded the Nobel Prize in physiology or medicine for his discovery of prions as a new biological principle of infection.

Prion Diseases

Prion diseases, or TSEs, are rare, infectious, lethal neurodegenerative diseases affecting humans as well as agricultural, captive and free-ranging animals. TSEs can be divided into

three etiological categories: sporadic, inherited, and acquired. Importantly, even the sporadic and genetic forms of the disease are experimentally transmissible.

One of several challenging aspects of prion diseases is the heterogeneity of clinical symptoms and histopathological phenotypes. This can make diagnosing these diseases a very difficult task. Currently, there are no proven treatments for prion diseases.

Human Prion Diseases

Human prion diseases are classified into CJD, GSS, FFI, and kuru. Most human prion diseases, 85%, are sporadic, meaning they have an unknown origin, which is often attributed to a spontaneous PrP^C to PrP^{Sc} conversion or to somatic mutation. Approximately 10–15% of human TSEs are inherited through mutations in the prion gene (PRNP) resulting in familial prion disease (familial CJD, GSS, and FFI). More than 30 disease-causing mutations in the open reading frame of PRNP have been characterized. Finally, less than 1% of human prion diseases are acquired by means of an infectious route. These rare instances, also referred to as acquired prion diseases, manifest in the form of variant CJD (vCJD) through the consumption of BSE contaminated beef; iatrogenic CJD (iCJD) by infected surgical procedures; or kuru through ritualistic cannibalism of the diseased (Collins *et al.*, 2004; Glatzel *et al.*, 2003; Mastrianni, 2010).

CJD

The neuropathological characteristics of CJD include neuronal loss, spongiform change, gliosis, and in some cases amyloid plaques.

Sporadic CJD

The commonest form, sporadic CJD (sCJD), results from a yet undefined, possibly stochastic event, in the central nervous system that induces PrP to misfold into a disease-causing form. It occurs with a worldwide incidence of between one and two deaths per one million people annually (Budka *et al.*, 2011). Clinical presentations of the disease vary, but in roughly 40% of patients the first symptom is cognitive dysfunction (often memory problems, language impairment and/or executive dysfunction) (Takada and Geschwind, 2013).

Variant CJD

The first case of variant CJD (vCJD) was recognized in the United Kingdom in 1995 (Will *et al.*, 1996). Since then, 228 cases of vCJD have been reported worldwide in 11 different countries, with the majority of cases found in the United Kingdom (Diack *et al.*, 2014). vCJD has been linked to the ingestion of BSE-infected meat, as it has been established that BSE and vCJD are the same prion strain (Bruce *et al.*, 1997). One prominent feature to distinguish between vCJD and sCJD is by analyzing PrP extracted from lymphoid organs such as tonsils. Likely due to its oral route of infection, vCJD shows PrP^{Sc} in the lymphoid organs, while sCJD does not (Frosch *et al.*, 2004).

The clinical presentation of vCJD differs from other forms of CJD. Patients with vCJD are generally younger, with a

median age of death of 28 years (as opposed to 68 years with sCJD) and duration of the disease is longer with a median of 14 months (compared to 7 months in sCJD) (Heath *et al.*, 2010; Pocchiari *et al.*, 2004). Patients usually suffer psychiatric symptoms early on in the disease course, commonly in the form of depression, anxiety, or apathy. Neurological symptoms arise as the disease progresses, including difficulty walking, unsteadiness, and involuntary movements; culminating at the complete loss of movement and death (Diack *et al.*, 2014).

Iatrogenic CJD

Although extremely rare, iatrogenic CJD (iCJD) results from the disease being accidentally transmitted through surgical procedures. More than 450 cases of iCJD have been recorded. The main sources have been contaminated growth hormone and dura mater grafts from cadavers with undiagnosed CJD; but a few cases have derived from neurosurgical instrument contamination, corneal grafts, gonadotrophic hormone, and secondary infection with vCJD transmitted by transfusion of blood products.

The infectious prion agent survives decontamination procedures that are standard procedure to destroy viruses and bacteria. It is hoped that the implementation of new sterilization techniques, exclusive use of synthetic growth hormone, combined with improved recognition of possibly infected individuals will end the outbreak of iCJD (Brown *et al.*, 2012).

It is interesting to note that iCJD, depending on the route of infection has markedly different incubation times. When iCJD occurs through direct transmission of CJD to the central nervous system (via corneal transplants, dura mater grafts, and contaminated surgical instruments during brain surgery), referred to as intracerebral transmission, the incubation period is 1.5–3.8 years. On the other hand, with iCJD transmitted through contaminated human growth hormone, a type of peripheral transmission, the incubation time is much longer, approximately 15 years.

Familial CJD

A small fraction of all CJD cases is due to point mutations on PRNP, resulting in familial CJD (fCJD). Experiments with fCJD showed for the first time that familial prion diseases are transmissible. This gives familial prion diseases the unique traits of being both inherited and transmissible (Gambetti *et al.*, 2003).

GSS

Gerstmann–Sträussler–Scheinker (GSS) is a slowly progressive hereditary autosomal dominant disease. It typically presents as a progressive ataxic disorder with late onset cognitive impairment. Onset of disease ranges from the fourth to the sixth decades with disease duration averaging 5 years. There is, however, substantial phenotypic variability among families (Arata *et al.*, 2006). GSS was the first human prion disease in which a mutation in PrP was described (Liberski, 2012).

FFI

Fatal familial insomnia (FFI) is a rare autosomal dominant inherited prion disease. It usually presents with progressive, severe insomnia, dysautonomia, and endocrine disturbances.

FFI is almost always caused by PrP^C mutations, but rare, sporadic cases have also been described, termed sporadic fatal insomnia (sFI). Disease onset usually occurs in the fifth and sixth decade of life and the mean duration of the disease is 18 months. Spongiform degeneration is rarely found in FFI patients, but neuronal loss and gliosis, specifically within the thalamus, is common (Capellari *et al.*, 2011; Pocchiari *et al.*, 2004).

Nearly 100 cases of FFI in almost 40 families have been reported from Italy, Germany, Austria, Spain, United Kingdom, France, Finland, the United States, Australia, Japan, China, and Morocco (Baldin *et al.*, 2009).

Animal Prion Diseases

TSEs in animals include scrapie of sheep and goats; BSE of cattle; CWD of cervids; transmissible mink encephalopathy (TME), feline spongiform encephalopathy, and ungulate spongiform encephalopathy (Kirkwood *et al.*, 1990; Marsh and Hadlow, 1992; Wells *et al.*, 1987; Williams and Young, 1980; Wyatt *et al.*, 1991). In addition to scrapie, the two most prevalent animal TSEs are BSE and CWD.

BSE

BSE also known as 'Mad Cow disease' is a prion disease that affects cattle. Clinical signs of BSE may include gait abnormalities (ataxia), tremors, aggressive behavior, apprehension, and hyperreactivity to stimuli.

BSE first appeared in the United Kingdom in the 1980s and quickly grew to epidemic proportions among cattle. The outbreak was fed by the practice of using meat and bone meal, which was then inadvertently contaminated with pathogenic prions, as a dietary supplement for the cattle. BSE has affected more than 180 000 cattle worldwide. A ban on the use of meat and bone meal in cattle feed has ultimately resulted in a decline of the epidemic (Ducrot *et al.*, 2008). The worst was realized when it became apparent that BSE had been transmitted to humans in the form of vCJD (Bruce *et al.*, 1997).

CWD

This TSE affects captive and free-ranging deer, elk, and moose in North America and South Korea. The origin of CWD is unknown. The potential for CWD transmission to humans is low and has yet to be documented (Beringue *et al.*, 2008; Sigurdson, 2008). Moreover, transgenic mice expressing the human, cattle, or sheep PrP^C did not develop TSE when inoculated with CWD prions (Tamguney *et al.*, 2006). CWD does, however, seem to spread readily among cervids and long-term effects of CWD on cervid populations and ecosystems could be very harmful, especially if the disease continues to spread.

The Prion Protein

The cellular form of the prion protein, PrP^C, has about 90% sequence similarity across mammals. It is expressed in almost all tissues, but the highest levels are found in the central

nervous system. Here, PrP^C is especially associated with synaptic membranes.

In humans, the prion gene (*PRNP*) encodes a 253 amino acid long precursor protein in a single, uninterrupted open reading frame. After translocation across the endoplasmic reticulum, the 22-amino acid N-terminal and 23-amino acid C-terminal signal peptide sequences are removed. This leaves a 209 amino acid long functional protein that is attached to the outer membrane surface of the cell by a glycosylphosphatidylinositol (GPI) anchor.

The precise function of PrP^C within the cellular context eludes researchers to this day. Its considerable conservation among mammals and high expression throughout the body suggest an important physiological role for PrP^C, however, PrP^C-deficient mice at first glance develop normally. Several possible functions for PrP^C have been proposed including signaling cascades, neuronal survival, apoptosis, oxidative stress, cell adhesion, cell differentiation, etc. (Grassmann *et al.*, 2013). It is known, however, that PrP^C has a high affinity for metals such as copper, zinc, and manganese (Garnett and Viles, 2003; Hornshaw *et al.*, 1995).

Structure

Much evidence now reinforces the idea that prions are principally or completely composed of an isoform of the normal host-encoded protein PrP^C. This abnormal isoform is designated PrP^{Sc} (Prusiner, 1991). PrP^{Sc} originates from PrP^C by a posttranslational mechanism (Caughey and Raymond, 1991). No consistent differences in amino acid sequence or posttranslational modifications have been found between PrP^C and PrP^{Sc} (Stahl *et al.*, 1993). It is thought that the differences between PrP^C and PrP^{Sc} only involve a conformational change and that PrP^{Sc} acts as a template for the conversion of PrP^C to PrP^{Sc}. The mechanism of conversion between the two is yet unknown, but discerning any conformational differences may help to better elucidate this mechanism.

The structure of the natively folded PrP^C was first available in 1996 and has been solved many times by X-ray crystallography and NMR since (Riek *et al.*, 1996; Surawicz and Apostol, 2011). These studies show PrP^C to have a mostly α -helical structure. This has been confirmed to be structurally equivalent to PrP^C found *in vivo* (Hornemann *et al.*, 2004).

PrP^C is attached to the outer cell membrane leaflet by a GPI anchor posttranslationally added. Additional posttranslational modifications include two variably occupied N-linked glycosylation sites at Asn181 and Asn197 as well as a stabilizing disulfide bridge between Cys 179 and Cys214.

Although the molecular structure of PrP^C is well characterized, that of PrP^{Sc} is still not well understood. Its tendency to aggregate and general insolubility have hindered attempts to elucidate its structure at high resolution. Generally, PrP^{Sc} is described as oligomeric in nature and abundant in β -sheet structures. Resolving the structure of PrP^{Sc} is of utmost importance in prion research today as the structural change from PrP^C to PrP^{Sc} is at the core of transmission, infection, and pathogenesis of prions (Requena and Wille, 2014).

Conversion and Replication

Structure plays a critical role in the prion saga, where PrP^C undergoes a structural change in conformation to convert it from the normal cellular protein found throughout the body to a misfolded form linked to disease, its infectious counterpart PrP^{Sc}. According to the 'protein-only' model, PrP^{Sc} itself is the infectious prion agent responsible for the transmissibility of prion disorders (Prusiner, 1998).

Two mechanisms have been proposed to explain how PrP^C is converted to PrP^{Sc}. In the heterodimer refolding model, (also known as the template assistance model), PrP^{Sc} is a monomer and thermodynamically favored, but kinetically inaccessible, conformer of PrP^C (Prusiner, 1991). In the rare event that a PrP^{Sc} molecule is spontaneously formed or delivered from an outside source, PrP^{Sc} would serve as a template for PrP^C by the formation of a heterodimer, misfolding PrP^C into the thermodynamically more stable PrP^{Sc}. This mechanism is possible, but there is no evidence for a stable PrP^{Sc} monomer, in fact, PrP^{Sc} is thought to be highly oligomeric (Silveira *et al.*, 2005).

The nucleation-polymerization model argues that PrP^{Sc} is less stable than PrP^C and that the limiting step to conversion is the formation of a PrP^{Sc} nucleus. Though the formation of this nucleus is not favored, once formed it is a stabilized aggregate. These aggregates of PrP^{Sc} then propagate by incorporating PrP^C monomers, which can easily add to the structure by adopting the PrP^{Sc} conformation. The rate-limiting nucleation step could be responsible for the lag phase in spontaneous conversion (Jarrett and Lansbury, 1993).

Transmission

A central characteristic of prion diseases is their transmissibility to other animals. However, the transmissibility of prions is not a straightforward process, in fact there seem to be some factors that hinder the ability of PrP^{Sc} to convert PrP^C, known as transmission barrier.

When transmitting an infectious prion, PrP^{Sc}, from one host to another identical host, where the amino acid sequences between PrP^{Sc} and PrP^C are identical, prion diseases are highly infectious. In this case the transmission barrier is very low or nonexistent. However, transmission of prions between species can be incomplete or with long incubation times, indicating some type of transmission barrier. This barrier is frequently linked to differences in the primary sequence of the PrP (Bruce *et al.*, 2002). Interestingly, a similar transmission barrier as is seen between species can be seen within the same species, often to a smaller extent, if the individuals express different PrP genotypes (Bossers *et al.*, 2000).

The transmission barrier has implications to human health. The barrier between humans and cattle with BSE is traversable, as evidenced by the many cases of vCJD. Fortunately, so far the transmission barrier seems to hold between humans and sheep/cervids as there are no known cases of humans developing a prion disease from scrapie or CWD.

The transmission barrier, however, is not a completely fixed characteristic. While initially there may exist a transmission barrier, several passages of PrP^{Sc} to identical hosts allows for the prions to stabilize. This process is known as prion

adaptation and it leads to characteristic, reproducible disease features of the prion disease (Thackray *et al.*, 2011). The process of adaptation leads to the generation of new prion strains.

Strains

Prion strains are molecules that share the same primary sequence of amino acids, but with differing incubation times or neuropathological/biochemical properties. Strains are believed to result from conformational differences in PrP^{Sc} (Telling *et al.*, 1996).

The existence of prion strains was first shown by the transmission of two isolates from scrapie-infected sheep into goats. It was observed that the goats showed two marked behavioral pathologies, a drowsy syndrome and a scratching syndrome, and that these behaviors were conserved upon subsequent passages in goats (Pattison and Millson, 1961). Later, five prion scrapie strains were isolated following inoculation into mice. These strains could be reliably recognized by histological parameters (degree of vacuolation and relative distribution of the damage within the brain) (Fraser and Dickinson, 1973). Additional studies have identified many prion strains with persisting characteristics after serial transmission in rodents (Solforosi *et al.*, 2013).

It was hard to imagine at the time that all of this diversity could be encoded simply within the protein structure of PrP^{Sc}. It was widely thought that the existence of strains was convincing evidence that some nucleic acid, which could mutate, must be involved. Even several genes within the host genome were suspected of influencing prion strains; but this was disproven when prion strains were propagated *in vitro* via non-genetic mechanisms (Bessen *et al.*, 1995).

Direct evidence for the molecular basis of prion strains was long wanting and many looked at prion strains as a key obstacle to the protein-only hypothesis. Ultimately, it was shown that hamsters infected with two strains of TME resulted in PrP^{Sc} molecules with distinct electrophoretic mobility (revealed as a specific pattern of bands on a Western Blot) and degree of resistance to protease digestion (Bessen and Marsh, 1994). The observed diversity is thought to arise from varying three-dimensional structures resulting in exposure of different combinations of proteinase-K cleavage sites found on the PrP (Parchi *et al.*, 2000). Unique banding patterns have also been described for protease-resistant PrP originating from vCJD and FFI (Collinge *et al.*, 1996; Telling *et al.*, 1996).

Prion strains are defined by their distinct prion disease phenotype (incubation time to disease onset, histopathological lesion profiles, and brain areas targeted) that persists upon serial transmission. Molecularly, strains have been described by their band pattern on a Western Blot after protease digestion and degree of protease digestion. In addition, pathological features are instrumental for fine characterization of closely related prion disorders.

Neurotoxicity

Perhaps the greatest mystery so far in the prion field is the mechanism by which PrP^{Sc} causes disease. TSEs are fatal

because they result in neuronal loss, extensive spongiform degeneration, and widespread synaptic damage, but the role of PrP^{Sc} in these processes is uncertain.

It is generally thought that PrP^{Sc} is the toxic species of prion diseases, responsible for the death of neurons. This is at first glance a reasonable assumption as PrP^{Sc} is the infectious agent able to transmit TSEs and its accumulation in the brain is generally seen as a hallmark of the diseases. However, much evidence has surfaced in favor of the 'dissociation' between the infectious agent and the toxic species (Halliday *et al.*, 2014).

In 1993, it was shown that PrP^{Sc} was harmless when inoculated into brains of mice devoid of PrP^C (PrP knockout (KO) mice) (Bueler *et al.*, 1993). This not only showed that PrP^C is essential for the propagation of PrP^{Sc}, but also that PrP^{Sc} itself is not neurotoxic. Another group used these resistant PrP KO mice and surgically grafted onto their brains neural tissue overexpressing PrP^C. When these chimeric mice were intracerebrally inoculated with PrP^{Sc} the grafted area accumulated high levels of PrP^{Sc} and showed grave histopathological characteristics typical of the disease. It was seen that a considerable amount of graft-derived PrP^{Sc} migrated to the host brain, but surprisingly no pathological changes were detected in the PrP KO tissue. This showed that brain tissue lacking PrP^C is not damaged by exogenous PrP^{Sc} (Brandner *et al.*, 1996).

It was also discovered that by genetically 'turning off' the production of PrP^C by neurons in mice already suffering from a prion infection is neuroprotective. By depleting endogenous neuronal PrP^C in already diseased mice the scientists were able to reverse early pathological changes, prevent neuronal loss and stop clinical progression of the disease. Interestingly, as PrP^{Sc} was still present in non-neuronal cells of the brain, PrP^{Sc} continued to accumulate outside neurons (to levels normally associated with terminally ill animals), but without the neurotoxic effects on the PrP^C-free neurons (Mallucci *et al.*, 2003). Similarly, by preventing PrP from attaching to the neuronal cell surface by removing the GPI anchor inhibits neurotoxicity, though once again PrP^{Sc} accumulates extraneuronally (Chesebro *et al.*, 2005).

These findings support the idea that PrP^{Sc} is not directly toxic to neurons, but that there is another mechanism involved. Currently, much work in the prion field is focusing on trying to understand the underlying cause(s) of neurotoxicity in prion diseases.

Conclusion

Prion diseases, although very rare, represent a new biological principle of infection and in fact, much recent research is indicating that the prion mechanism of disease may not be limited to prion diseases. Many neurodegenerative diseases, such as Alzheimer's disease, Parkinsons disease, and amyotrophic lateral sclerosis, may share with prion diseases an analogous mechanism of conversion, replication, and propagation (Prusiner, 2012). Consequently, self-propagating proteins such as prions will likely continue to be a source of scientific interest for some time.

INTRACELLULAR INFECTIOLOGY: CELL PROCESSES

Cellular Responses to Infections in *Caenorhabditis elegans*

Caenorhabditis elegans as a Model System to Study Responses to Pathogens

Caenorhabditis elegans is a powerful experimental organism for a number of traits that facilitate genetic and genomic analysis, including the hermaphroditic lifestyle, short 2–3 week lifespan, and small genome, which offers an ideal compromise between complexity and tractability. Unlike bacteria, yeast, or other single-celled organisms, *C. elegans* has muscles, nerves, sexual organs, and guts, in spite of its one millimeter long body. It reacts to touch, can recognize odors, and exhibits different behaviors. In nature, *C. elegans* is found in the soil and decaying organic matter. To date, more than 40 microbes have been shown to be pathogenic to *C. elegans*, including bacteria, fungi, and viruses. The major routes of infection are through the intestine and the epidermis. Because the nematode lacks professional immune cells, intestinal and epidermal epithelial cells serve as the primary defense against pathogens, as they are in direct contact with different microbes. Despite lacking adaptive immunity, *C. elegans* can mount protective responses to pathogen infection by avoiding certain pathogens or by triggering evolutionarily conserved signaling pathways. Activation of these cellular signaling pathways can lead to production of immune effectors such as lectins, lysozymes, lipases, and

antimicrobial peptides, which act directly to fight off the invading pathogens. The defensive response that results in activated signaling pathways and induced immune effectors is pathogen-specific, indicating that the nematode is able to distinguish different infecting microbes.

Overview of *C. elegans* Pathogens

Caenorhabditis elegans can be infected in its natural environment and in the laboratory setting by a large number of pathogens, including Gram negative bacteria, Gram positive bacteria, fungi, and viruses. These pathogens may vary in their mode of infection, site of replication and host responses they induce. **Figure 1** illustrates site and mode of infection utilized by a number of the most highly studied pathogens in *C. elegans*.

The majority of bacteria and fungi remain extracellular. Gram negative pathogens, such as *Salmonella enterica* and *Pseudomonas aeruginosa*, colonize the digestive system of *C. elegans* causing lethal infections (Aballay *et al.*, 2000; Tan *et al.*, 1999). *Pseudomonas aeruginosa* can kill *C. elegans* using toxins in a matter of hours by a process termed ‘fast killing’ (Mahajan-Miklos *et al.*, 1999). It can also kill nematodes in 2–4 days by an infectious-like process termed ‘slow-killing,’ which requires bacterial

Figure 1 *Caenorhabditis elegans* pathogens colonize different tissues of the nematode. Gram negative bacteria, green; Gram positive bacteria, blue; fungi, yellow; viruses, orange. Natural pathogens of *C. elegans* are marked with superscript *n*.

replication in the intestinal lumen of the host (Tan *et al.*, 1999). Other Gram negative bacteria, such as *Microbacterium nematophilum*, and *Yersinia pestis* strains incapable of forming biofilms, also colonize the digestive tract, but cause rectal inflammation in the digestive tract (Hodgkin *et al.*, 2000; Styer *et al.*, 2005). *Yersinia pestis* strains capable of forming biofilm cover the mouth of *C. elegans* and prevent feeding, reminiscent of *Y. pestis* infection of plague carrier fleas (Darby *et al.*, 2002). Gram positive bacteria such as *Enterococcus faecalis* and *Staphylococcus aureus* also colonize the intestine (Irazoqui *et al.*, 2010; Garsin *et al.*, 2001). An interesting aspect of *S. aureus* infection is that it causes extensive loss of intestinal microvilli of the host and rectal inflammation (Irazoqui *et al.*, 2010).

Fungal pathogens can set up infection in the intestine of the nematode or the epidermis. The yeast form of the human opportunistic pathogen *Cryptococcus neoformans* accumulates in the nematode intestine and causes a lethal infection (Mylonakis *et al.*, 2002). *Drechmeria coniospora* is a natural fungal pathogen of *C. elegans* that enters through the cuticle and penetrates all body tissues (Couillault *et al.*, 2012; Jansson, 1994). *Candida albicans*, a fungus that causes nosocomial infections in humans, is pathogenic to *C. elegans* in both its hyphal and yeast forms. In turn, nematodes elicit distinct responses depending upon the site of infection (Pukkila-Worley *et al.*, 2009; Breger *et al.*, 2007).

A small number of natural pathogens can cause intracellular infections in *C. elegans*. Examples include *Nematocida parisii*, which is a microsporidian parasite related to fungi, and a natural pathogen of *C. elegans* (Troemel *et al.*, 2008; Felix and Duveau, 2012). Orsay virus and other viruses of the nodoviridae family cause intracellular invasion in the intestine of *C. elegans* and related species (Felix *et al.*, 2011; Franz *et al.*, 2014).

Pathogen Recognition by *C. elegans*

The mechanisms by which *C. elegans* identifies pathogens remain elusive. In plants and higher animals, pathogen recognition is mainly mediated by a set of PRRs that detect conserved pathogen-derived molecules, known as pathogen-associated molecular patterns (PAMPs) or MAMPs. The best characterized PRRs are a family of conserved transmembrane Toll-like receptors (TLRs) that recognize various microbial products, such as bacterial cell-wall components and flagellin, and trigger multiple defense response pathways. The genome of *C. elegans* does not encode the majority of known PRRs and lacks genes of some key components of the TLR pathways such as NF- κ B homologs and the TLR adaptor MyD88. Nematode orthologs of a single Toll-like receptor (TOL-1), TNF receptor associated factor-1 (TRF-1), Pelle and IL-1R-associated kinases (PIK-1) and inhibitor of NF- κ B (IKB-1) do not seem to play key roles in immunity. However, it is worth noting that TOL-1 has been implicated in immune signaling against *S. enterica* (Tenor and Aballay, 2008) and that TIR-1, a scaffold protein containing Toll/IL-1R (TIR) protein-protein interaction domain, is involved in antimicrobial defense against a variety of *C. elegans* pathogens (Liberati *et al.*, 2004; Couillault *et al.*, 2004). *Caenorhabditis elegans* is also capable of activating immune pathways when exposed to heat-killed *S. aureus* and *C. albicans*, suggesting that the nematode can detect pathogenic

microbes via MAMP recognition (Irazoqui *et al.*, 2010; Pukkila-Worley and Ausubel, 2012).

While MAMP/PRR interactions capable of eliciting immune responses in *C. elegans* remain elusive, emerging evidence supports the notion that the nematode can recognize pathogen attack through the detection of disturbances of cellular homeostasis. *Caenorhabditis elegans* appears to have evolved cellular surveillance systems to monitor its core cellular activities and interpret disruption of these activities as evidence of pathogen attack. The innate immunity elicited by this kind of indirect recognition is similar to effector-triggered immunity (ETI) that was originally demonstrated in plants (Jones and Dangl, 2006) and later found conserved across invertebrate and vertebrate animals (Boyer *et al.*, 2011; Kleino and Silverman, 2012). An example of ETI in *C. elegans* is its response to a virulence factor of *P. aeruginosa*, Exotoxin A (ToxA). Upon infection with *P. aeruginosa*, ToxA enters the intestinal epithelial cells, likely via endocytosis, and inhibits protein translation by modifying elongation factor 2 via ADP-ribosylation, which triggers the host to up-regulate immune defense genes (Dunbar *et al.*, 2012; McEwan *et al.*, 2012). Besides protein translation, disruption of many other cellular functions such as mitochondrial respiration, ubiquitin-proteasome system activity, or actin cytoskeleton and microtubule dynamics, results in activation of detoxification and immune responses in *C. elegans* (Melo and Ruvkun, 2012; Bakowski *et al.*, 2014). Pore-forming toxins (PFTs), the single largest class of proteinaceous bacterial virulence factors that perforate host cell membranes, can also trigger ETI in the nematode, although the precise molecular mechanisms remain unknown (Engelmann and Pujol, 2010). It has been suggested that the host cells can sense disruption of cell membrane, potassium efflux or calcium influx and respond with antimicrobial signaling and membrane repair pathways (Los *et al.*, 2013; Los *et al.*, 2011). ETI offers *C. elegans* an effective and versatile strategy to detect and distinguish pathogens from surrounding microbes. On the one hand, this allows the nematode to combat a wide variety of microbes without evolving the full repertoire of PRRs; on the other hand, it remains to be addressed how the nematode can distinguish infecting microbes if different pathogens disrupt the same cellular processes, as immune responses are not only pathogen-shared but also pathogen-specific (Wong *et al.*, 2007; Shivers *et al.*, 2008; Alper *et al.*, 2007; Irazoqui *et al.*, 2010; Schulenburg *et al.*, 2008).

G protein-coupled receptors (GPCRs) may play a direct or indirect role in pathogen recognition in *C. elegans*. The nematode uses neuronal GPCR-mediated signaling to sense bacterial compounds and to respond by avoiding pathogens and activate immune pathways (Sun *et al.*, 2011; Styer *et al.*, 2008; Pradel *et al.*, 2007; Reddy *et al.*, 2009). Furthermore, a GPCR that functions in the epidermis activates innate immunity by recognizing an endogenous ligand. This ligand potentially acts as a danger molecule to alert the organism of fungal infections (Zugasti *et al.*, 2014).

Immune Effectors

Upon infection, a number of immune effectors are produced in *C. elegans* and confer the nematode protective immunity

Table 1 Common immune effectors in *Caenorhabditis elegans*

Immune effector	Description	Gene family	References
Antibacterial factor (ABF)	Small cationic peptides similar to human defensins ● Antimicrobial activity	<i>abf-1</i> to <i>abf-6</i>	Kato <i>et al.</i> (2002)
Caenacin	Putative antimicrobial peptides, structurally related to neuropeptide-like proteins antimicrobial activity ● Antimicrobial activity	<i>cnc-1</i> to <i>cnc-11</i>	Zugasti and Ewbank (2009)
Caenopore	A family of proteins containing saposin-domain, similar to protozoan amoebapores, mammalian NK-lysin, and granulysin ● Antibacterial activity ● Membrane permeability ● Pore-forming activity	28 spp genes encoding 33 different caenopores	Roeder <i>et al.</i> (2010); Banyai and Pathy (1998); Hoeckendorf and Leippe (2012); Hoeckendorf <i>et al.</i> (2012)
C-type lectin	Proteins that contain one or more C-type lectin-like domains (CTLD) and recognize complex carbohydrates on cells and tissues ● Antimicrobial activity ● Contribute pathogen specificity of immunity	278 genes encoding CTLD proteins	Drickamer and Dodd (1999); Takeuchi <i>et al.</i> (2008); Schulenburg <i>et al.</i> (2008); Simonsen <i>et al.</i> (2012)
CUB domain protein	The CUB domain is a structural motif of approximately 110 residues. They resemble immunoglobulin and occur in large gene clusters ● Antimicrobial activity	More than 50 genes encoding CUB domain proteins	Bork and Beckmann (1993); Bolz <i>et al.</i> (2010)
Lysozyme	Lysozymes are glycosyl hydrolase enzymes present in microbes, insects, plants, and animals ● Degrade bacterial cell wall ● Antimicrobial activity	10 protist type lysozyme encoding genes (<i>lys-1</i> to <i>lys-10</i>) and 5 invertebrate type lysozyme encoding genes (<i>ilys-1</i> to <i>ilys-5</i>)	Schulenburg and Boehnisch (2008); Mallo <i>et al.</i> (2002); Jensen <i>et al.</i> (2010); Marsh <i>et al.</i> (2011)
Neuropeptide-like protein (NLP)	The NLPs are a diverse group of neuropeptides that have little similarity among them ● Acts as neurotransmitters ● Antimicrobial activity	42 genes encoding NLPs	Nathoo <i>et al.</i> (2001)

against microbial pathogens (Table 1). These effectors either directly inhibit the growth of invading pathogens or counteract their effects on host cells.

Antibacterial Factors (ABFs)

ABF-1 to ABF-6 in *C. elegans* are small cationic peptides similar to human defensins. ABF-2 has antimicrobial activity against Gram negative bacteria, Gram positive bacteria, and yeast (Kato *et al.*, 2002). ABF-1 and ABF-2 are expressed in the pharynx of *C. elegans*, which is one of the first organs that gets in direct contact with pathogens, and their expression requires TOL-1, and cell death receptor CED-1.

Caenacins

These are putative antimicrobial peptides, structurally related to neuropeptide-like proteins. Some of these genes are up-regulated in the epidermis following infection with the fungal pathogen *D. coniospora*. Up-regulation of caenacins in the epidermis requires neurally produced TGF β homolog DBL-1 (Zugasti and Ewbank, 2009). In addition, overexpression of caenacins enhances *C. elegans* immunity against *D. coniospora*.

Caenopores

Caenopores are a family of proteins containing a saposin domain in *C. elegans*, similar to protozoan amoebapores,

mammalian NK-lysin and granulysin. *Caenorhabditis elegans* has a group of 28 *spp* genes that encode 33 different caenopores (Roeder *et al.*, 2010). Antibacterial, membrane-permeabilizing, and pore-forming activities have been demonstrated for SPP-1, SPP-3, SPP-5, and SPP-12 (Banyai and Pathy, 1998; Roeder *et al.*, 2010; Hoeckendorf *et al.*, 2012; Hoeckendorf and Leippe, 2012). SPP-1 protects *C. elegans* against *S. enterica* and *P. aeruginosa*. Down-regulation of SPP-1 by *P. aeruginosa* is under the control of the FOXO transcription factor DAF-16.

C-type Lectins

C-type lectins are a group of proteins that contain one or more C-type lectin-like domains (CTLD) and that recognize complex carbohydrates on cells and tissues (Drickamer and Dodd, 1999; Takeuchi *et al.*, 2008). 278 genes encoding CTLD proteins are present in the *C. elegans* genome (Schulenburg *et al.*, 2008). More than 60 CTLD proteins are induced during pathogen infection. Distinct expression profiles of CTLD genes during different infections indicate that these proteins might contribute to pathogen specificity of *C. elegans* immune responses. For instance, RNAi knockdown of *clec-17*, *clec-60* and *clec-86* caused enhanced susceptibility to *M. nematophilum* (O'Rourke *et al.*, 2006). Also, knockdown of *clec-65* or *clec-70* resulted in enhanced susceptibility to *Escherichia coli* LF82 or *S. aureus*, respectively (Simonsen *et al.*, 2011; Irazoqui *et al.*, 2010). Simultaneous overexpression of *clec-60* and *clec-61*, or *clec-70* and *clec-71* led to increased resistance to *S. aureus* but decreased resistance to *P. aeruginosa* (Irazoqui *et al.*, 2010). C-type lectins often bind carbohydrates in a Ca^{2+} -dependent manner. However, a recent study revealed that CLEC-39 and CLEC-49 directly recognize live *Serratia marcescens* in a Ca^{2+} -independent manner, suggesting a nonclassical recognition of *S. marcescens* by both CTLD proteins (Miltch *et al.*, 2014).

CUB Domain Proteins

More than 50 genes in the *C. elegans* genome encode proteins containing a CUB (C1r/C1s, Uegf, and Bmp1) domain, which is a structural motif of about 100 residues (Bork and Beckmann, 1993). RNAi inhibition of three of the CUB genes (F08G5.6, F20G2.5, *dct-17*) enhances *C. elegans* susceptibility to *P. aeruginosa* and RNAi inhibition of two other CUB genes (C17H12.8 and C32H11.12) enhances *C. elegans* susceptibility to *Y. pestis* infection. Interestingly, CUB genes that are usually upregulated in response to bacterial infections, are down-regulated in response to fungi such as *C. albicans* and *D. coniospora* (Simonsen *et al.*, 2012).

Lysozymes

Lysozymes are glycosyl hydrolase enzymes that degrade bacterial cell walls and that are present in both plants and animals. The *C. elegans* genome has 10 protist type lysozyme encoding genes (*lys-1* to *lys-10*) and 5 invertebrate type lysozyme encoding genes (*ihys-1* to *ihys-5*) (Schulenburg and Boehnisch, 2008). Many lysozyme genes are expressed in the intestine and upregulated in response to microbial infections.

RNAi inhibition of *lys-1* causes enhanced susceptibility to *S. aureus*, while overexpression of *lys-4* and *lys-5* increases resistance to *S. aureus* (Mallo *et al.*, 2002; Jensen *et al.*, 2010). Overexpression of *lys-4* enhances resistance to *S. marcescens* (Mallo *et al.*, 2002). *lys-7* mutants are also more susceptible to *C. neoformans* infection but resistant to *S. typhimurium* infection (Marsh *et al.*, 2011).

Neuropeptide-Like Proteins

Neuropeptides are bioactive peptides that play a role in synaptic signaling. *Caenorhabditis elegans* has 32 genes encoding neuropeptide-like proteins (NLPs) (Nathoo *et al.*, 2001). Some of the NLPs encoding genes are upregulated during microbial infection. NLP-31 has antimicrobial activity *in vitro* and NLP-29 is expressed in the intestine and hypodermis (Couillault *et al.*, 2004). Up-regulation of nlp-29 cluster (6 genes) in the hypodermis during *D. coniospora* infection requires signaling molecules such as TIR-1, PMK-1/p38 MAPK and DCAR-1/GPCR.

Immune Signaling Pathways

Detection of pathogen attack leads to activation of cellular signaling pathways that induce expression of defensive genes to limit microbial growth, destroy invading microbes, detoxify xeno/endobiotics, and repair damage. These pathways include innate immune and stress response pathways activated in various tissues during infection with bacterial or fungal pathogens (Figures 2 and 3). Recent studies demonstrated the complexity and specificity of these responses: different signaling pathways regulate expression of distinct but overlapping sets of effector genes, individual pathogens induce genes controlled by multiple pathways, and the set of genes regulated by each pathway is also pathogen-specific.

The p38 MAPK Pathway and Related Pathways

The conserved p38 MAPK pathway plays a major role in the antimicrobial response of *C. elegans*. Forward and reverse genetic studies have demonstrated that the p38 MAPK pathway is required for immunity against a variety of pathogens and xenobiotics, including Gram negative and positive bacteria, fungi, PFTs, and many types of stress such as oxidative stress and heavy metal stress (Ermolaeva and Schumacher, 2014; Pukkila-Worley and Ausubel, 2012). This pathway includes the TIR domain protein TIR-1, neuronal symmetry family member 1 (*nsy-1*), SAPK/ERK kinase 1 (*sek-1*) and p38 MAPK family member 1 (*pmk-1*) (Kim *et al.*, 2002, 2004). Signal is transduced in the form of protein phosphorylation, where NSY-1 phosphorylates SEK-1, which in turn phosphorylates PMK-1. TIR-1 and two protein kinases PKC δ and PKD act upstream of NSY-1 (Liberati *et al.*, 2004; Ziegler *et al.*, 2009; Ren *et al.*, 2009). It has also been demonstrated that *C. elegans* ATF-7, a transcription factor orthologous to mammalian ATF2, functions downstream of PMK-1 as a repressor of PMK-1-regulated genes, and undergoes a switch to an activator upon phosphorylation by PMK-1 (Shivers *et al.*, 2010).

Figure 2 Cellular responses to bacterial infection in *C. elegans*. Replication and accumulation of Gram negative bacteria in the intestine leads to activation of many signaling pathways. Some of the better studied pathways include p38 MAPK, insulin signaling involving FOXO transcription factor Daf-16 as well as UPR in the intestinal cells. These produce effector molecules including antimicrobial molecules, chaperones etc. The site of activation of beta catenin or the ERK MAPK pathway is not known.

Figure 3 Cellular responses to fungal infection in *C. elegans*. Invasion of epidermis by hyphal form of fungus *Drechmeria coniospora* leads to induction of defenses in that tissue. The p38 MAPK pathway regulates antimicrobial peptides such as NLP genes in the epidermis while the TGFbeta pathway regulates anti-fungal products such as caenacins, C-type lectins and lysozymes. DCAR-1, a G protein-coupled receptor (GPCR) in the epidermis, regulates NLP gene expression partly through the PMK-1 pathway.

Activation of the p38 MAPK pathway induces expression of a set of secreted immune response genes. Several microarray studies showed that genes upregulated by PMK-1 include those encoding proteins containing CUB-like domains, C-type lectins, antibacterial peptides, lysozymes, NLPs, and caenacins. Besides p38, two other MAPKs, extracellular signal-regulated kinase (ERK) and c-Jun N-terminal kinase (JNK), are also involved in the nematode's defense to infections. Upon infection with *M. nematophilum*, the ERK pathway is activated and mediates a protective response by inducing production of C-type lectins, lysozymes, proteases, and other defense-related proteins (Nicholas and Hodgkin, 2004; O'Rourke et al., 2006).

The JNK pathway is a key regulator of the transcriptional and functional responses to bacterial PFTs (Kao et al., 2011).

The DAF-2/DAF-16 Pathway

The DAF-2/DAF-16 pathway is well known for its regulation on the lifespan of *C. elegans*, and also plays important roles in the immune response to infection by several bacteria. Activation of the DAF-2 receptor by an agonist ligand, such as the insulin-like peptide DAF-28, activates a phosphorylation cascade that results in the phosphorylation of the FOXO family

transcription factor DAF-16. Phosphorylated DAF-16 is retained in the cytoplasm. In *daf-2* mutants or in the presence of an antagonist ligand such as INS-1, un-phosphorylated DAF-16 translocates into the nucleus, where it regulates expression of a wide variety of genes (Lin *et al.*, 2001). It has been suggested that the PMK-1 and DAF-16 pathways act in parallel to promote immunity. While PMK-1 controls both basal and infection-induced expression of pathogen response genes, DAF-16 regulates a constitutively expressed response or a general stress response to microbes (Troemel *et al.*, 2006; Shivers *et al.*, 2008). This is in agreement with the role of DAF-16 in regulating the expression of many genes involved in resistance to various forms of stress, including heat, oxidative stress, hypoxia, osmotic stress, heavy metal toxicity, ultraviolet radiation, proteotoxicity, and microbial infection (Murphy and Hu, 2013). A number of antimicrobial effectors are regulated by DAF-16, including lysozymes LYS-7 and LYS-8, the saposins SPP-1, SPP-9 and SPP-12, DUF-23, and C-type lectins (Shivers *et al.*, 2008; Murphy and Hu, 2013). Most of these effectors appear to be secreted proteins that function to disrupt microbial cell membranes.

The DBL-1 Pathway

The DBL-1 pathway in *C. elegans* is homologous to the mammalian TGF β cascade, and was first described as involved in resistance to infection by *P. aeruginosa* and *S. marcescens* (Tan, 2001; Mochii *et al.*, 1999; Mallo *et al.*, 2002). The TGF β family ligand DBL-1 binds membrane-anchored heterodimeric DAF-4/SMA-6 receptor, leading to the phosphorylation and activation of the cytoplasmic signal transducer SMAD complex (SMA-2, -3 and -4); the transducer then translocates into the nucleus, where it activates gene expression. *dbl-1* mutants exhibit increased susceptibility to infection with *S. marcescens*, and the DBL-1 pathway up-regulates the expression of many defense genes, including lectins and lysozymes (Mallo *et al.*, 2002). Upon infection with fungus *D. coniospora*, *dbl-1* gene is also required for induction of *cnc-2* expression (Zugasti and Ewbank, 2009).

The Unfolded Protein Response Pathway

In the endoplasmic reticulum (ER), proteostasis surveillance is mediated by the unfolded protein response (UPR). ER is an important intracellular organelle in which newly synthesized transmembrane and secretory proteins are folded, assembled and matured. ER homeostasis is critical for ensuring proper folding and release of modified proteins to the Golgi. In response to pathogen infection, increased demands on the protein folding machinery causes stress in the ER, which activates a series of UPR pathways to restore ER homeostasis. Activation of UPR in *C. elegans* is required for defense against a variety of pathogens including *B. thuringiensis*, *S. enterica* and *P. aeruginosa* (Bischof *et al.*, 2008; Haskins *et al.*, 2008; Richardson *et al.*, 2010). UPR was found to be regulated by the p38, JNK and MAPK pathways in response to PFTs (Bischof *et al.*, 2008; Kao *et al.*, 2011). Interestingly, activation of UPR is also required by p38 MAP kinase PMK-1 mediated defense against *P. aeruginosa* (Richardson *et al.*, 2010). Upon infection

with *S. typhimurium*, the apoptotic receptor CED-1 activates the expression of *pqn/abu* genes in the noncanonical UPR pathway to promote immune response (Haskins *et al.*, 2008). In light of recent studies indicating that there is a strong developmental regulation of certain *abu/pqn* genes (George-Raizen *et al.*, 2014), further investigation will be required to fully address whether such genes are part of the UPR and whether their role in resistance to pathogen infection is related to cuticle and pharynx integrity rather than UPR. A recent study by Glover-Cutter *et al.* demonstrated that SKN-1, the *C. elegans* homolog of Nrf1/2/3 that functions in oxidative stress resistance and longevity, transcriptionally regulates core UPR transcription factors and downstream effectors in the ER-stress response, and the UPR plays a role in activation of the antioxidant/detoxification response (Glover-Cutter *et al.*, 2013).

Response Pathways to Intracellular Pathogen Infections

Unlike in the case of bacterial intestinal infections, canonical defense pathways, such as p38 MAPK and insulin/insulin-like growth factor signaling pathways, do not appear to play roles in resistance to the intracellular pathogen *N. parisii* (Troemel *et al.*, 2008). Ubiquitin-mediated pathways, the proteasome, and xenophagy components are involved in host response and defense against *N. parisii* infection (Bakowski *et al.*, 2014). The ubiquitin-mediated response is also important for defense against the Orsay virus, another natural intracellular pathogen of *C. elegans* (Bakowski *et al.*, 2014).

Both natural and nonnatural viral infection models have been established in *C. elegans*. Studies using laboratory introduced viruses such as Flock House virus (FHV), vesicular stomatitis virus (VSV), and vaccinia virus (VV) have identified a prominent role for the RNA interference (RNAi) machinery in viral restriction, a conserved defense mechanism that was first characterized in plants (Ermolaeva and Schumacher, 2014). These studies confirmed that the RNAi pathway is important for protection from viral infection. *Caenorhabditis elegans* mutants with defective RNAi had higher viral load, while mutants with hyperactive RNAi responses had lower viral load. More recently, three novel RNA viruses, Orsay, Santeuil, and Le Blanc viruses, were found to be able to naturally infect nematodes (Felix *et al.*, 2011; Franz *et al.*, 2012). All three viruses are distantly related to nodaviruses and cause morphological abnormalities in the nematode intestine (Franz *et al.*, 2014). The RNAi pathway has also been implicated in the defense against these natural viruses. Nematode mutants lacking RNAi factors (RDE-1, RDE-4, RNaseD MUT-7, or dicer-related helicase DRH-1) had an elevated infection load.

Conclusions and Perspectives

Caenorhabditis elegans has been proven to be an excellent model system for studying host-pathogen interactions. Although it lacks typical MAMP/PRR-mediated pathogen recognition mechanisms, it can distinguish pathogens from innocuous microbes through surveillance-mediated recognition mechanisms that are capable of detecting disturbances in cellular homeostasis. This ancient mechanism has been

evolutionarily conserved across species. For example, inhibition of host protein synthesis by secreted *Legionella pneumophila* virulence factors activates an innate immune response in mouse macrophages (Fontana *et al.*, 2011). *Escherichia coli*-encoded toxin CNF1 catalyzes deamidation of a host RhoGTPase and triggers NF- κ B immune responses in both insects and mammalian cells (Boyer *et al.*, 2011). Given that there are numerous microbial virulence factors and toxins in the environment aiming at crippling host functions, monitoring their own cellular activities offers the hosts a very effective and economic strategy to detect threats. The only caveat with this hypothesis is that it cannot explain how hosts distinguish between infecting pathogens and mount a pathogen-specific response if different pathogens disrupt the same cellular functions.

There is a complex signaling network in *C. elegans* that is activated in response to microbial infection and stress. This network includes several highly conserved signaling pathways, such as the MAPK pathways, the DAF-2/DAF-16 pathway, and the TGF- β /DBL-1 pathway. There are extensive interplays among immune signaling pathways, between immunity and stress response pathways, and between immunity and longevity pathways. For example, genetic analysis showed that the p38 MAPK pathway contributes to the enhanced longevity regulated by the DAF-2/DAF-16 pathway (Troemel *et al.*, 2006). p38 MAPK signaling also mediates response to oxidative stress generated by the dual oxidase Ce-Duox1/BLI-3 during infection in *C. elegans* (Hoeven *et al.*, 2011). The complexity and specificity of these pathways and their interactions make elucidating molecular details of innate immunity a challenging task, especially in humans. The simplicity of *C. elegans* anatomy and the wealth of genetic and genomic tools for *C. elegans* research make the nematode an outstanding system to dissect host responses to microbial infections at the cellular and molecular levels in a multicellular organism.

EDITORS-IN-CHIEF

Ralph A. Bradshaw received his BA in Chemistry from Colby College in 1962 and his PhD from Duke University in Biochemistry in 1966. He performed postdoctoral research at Indiana University and the University of Washington and in 1969 joined the faculty of Washington University School of Medicine in the Department of Biological Chemistry.

In 1982, he became Professor and Chair of the Department of Biological Chemistry at University of California, Irvine. He remained on the faculty of UCI for 25 years, the last 10 in the Department of Physiology and Biophysics. In 2006, he retired as Professor Emeritus at UCI and became Professor of Pharmaceutical Chemistry at the University of California San Francisco. His research has focused upon protein chemistry and the structure and function of growth factors and their receptors. He and his colleagues have determined the partial or complete sequence of over 75 proteins.

Philip D. Stahl is E. Mallinckrodt Jr. Professor Emeritus at Washington University School of Medicine in St. Louis, MO. He was educated at West Virginia University with post-doctoral work at Vanderbilt University. He served as Head of the Department of Cell Biology and Physiology and Director of the Division of Biology and Biomedical Sciences at Washington University. He has been the recipient of many awards including a MERIT award from the NIH and the WICB Senior Recognition award given by the American Society for Cell Biology in recognition of his work supporting the advancement of women in science. Among StahlLab contributions are the discovery of the lysosomal enzyme clearance pathway now implemented in the treatment of lysosomal storage disease, discovery of the innate immune receptor, the mannose receptor, discovery of the exosome secretion pathway, and the role of Rab5 and Arf6 in endocytosis.

Currently his research focuses on endocytosis, signal transduction, and exosome biogenesis and secretion.

VOLUME EDITORS

Gerald Hart is the Director and DeLamar Professor of Biological Chemistry at Johns Hopkins Medical School. He began his research on glycoconjugates about 40 years ago as a graduate student, and he has been active in the field of Glycobiology ever since. Among his research accomplishments, he determined the minimal sequence requirements for N-linked glycosylation while a postdoc in William Lennarz's lab, and he collaborated with Paul Englund's group at Johns Hopkins to elucidate the biosynthetic pathway for GPI-anchors. In the early 1980s, while probing cells with glycosyltransferases, Hart's laboratory discovered cytoplasmic and nuclear protein glycosylation by O-linked N-acetylglucosamine (O-GlcNAc) (e.g., *Journal of Biological Chemistry* 259: 3308; *Journal of Biological Chemistry* 261: 8049). Since that time, the Hart laboratory has published nearly 200 papers on O-GlcNAcylation, identifying and cloning the enzymes controlling cycling, characterizing O-GlcNAcylation and its interplay with phosphorylation on hundreds of proteins, and they have developed many of the tools and methods in use today to study this modification. In

1989, Hart founded the leading journal in the field, *Glycobiology*, serving as Editor-in-Chief until 2001. Hart received the first International Glycoconjugate Organization (IGO) Award in 1997, the Karl Meyer Award from the Society for Glycobiology in 2006, and served as the 2009–2011 president of the IGO. Hart is currently an Associate Editor for *The Journal of Biological Chemistry* and an Associate Editor for *Molecular and Cellular Proteomics*. To date, Hart has published about 263 papers, all in the area of glycosciences. H factor=84.

Bruno Goud studied biochemistry and immunology at the Ecole Normale Supérieure de Cachan and the University of Paris. He received his PhD in 1981 under the mentorship of Jean-Claude Antoine and Stratis Avrameas at Institut Pasteur and did postdoctoral work under the mentorship of Peter Novick at Yale University. In 1995, he established an independent research group in the Department of Cell Biology at the Institut Curie in Paris. The main focus of his studies is the regulation of intracellular transport and membrane trafficking in eukaryotic cells. In particular, his group is working on the functions of Rab GTPases, the mechanisms that sustain the global organization of intracellular compartments and the functions of myosins in membrane traffic. Since 2000, he has also developed original *in vitro* approaches to unravel physical parameters such as membrane tension or membrane curvature that underlie transport processes.

Bruno Goud is a recipient of an ERC (European Research Council) Advanced grant (2013). He is a member of the European Molecular Biology Organization (EMBO). He has been the Head of the Department of Cell Biology of Institut Curie since 2003.

Graça Raposo received her PhD in 1989 in Membrane Biology and Immunology at the University of Paris VII where she specialized in electron microscopy and membrane biology. From 1990 to 1995 she was a postdoctoral fellow at the Immunology Center in Marseille and then in the Department of Cell Biology, Utrecht University, The Netherlands. She is the deputy Director of the Department of Cell Biology at Institut Curie and Director of the Training unit. Her major research interests focus on the biogenesis and functions of exosomes and lysosome related organelles with implications in neurodegenerative disorders, lysosomal diseases, and cancer. Her group have started to unravel the cellular and molecular mechanisms regulating the biogenesis of melanosomes, the lysosome related organelles of epidermal melanocytes, studies that open a new avenue to modulate pigmentation in health and disease. In 2012 she was awarded the CNRS Silver Medal and in 2013 the Descartes Huygens Price from the Royal Dutch Academy of Sciences. She is a member of the European Molecular Biology Organization (EMBO).

Alan Ezekowitz, MBChB, DPhil, FAAP, is Co-Founder, President, and CEO of Abide Therapeutics, a company cofounded by Professors Dale Boger and Ben Cravatt from the Scripps Research Institute. He was previously Senior Vice President and Franchise Head, Bone, Respiratory, Immunology, Endocrine, Dermatology and Urology at Merck Research Laboratories. At Merck, he was responsible for the overall scientific direction of the drug discovery and development process. Prior to Merck, Dr. Ezekowitz was Chief of Pediatric Services at the Massachusetts General Hospital for Children and the Partners Healthcare System and the Charles Wilder Professor of Pediatrics at the Harvard Medical School. He chaired the committee that led to the establishment of the Academy at the Harvard Medical School where he served as a Scholar and Founding member. He served on the Board of Directors of the Partners Healthcare System and Massachusetts General Physicians Organization. In 2008 he was honored with the establishment R. Alan Ezekowitz Professorship in Pediatrics at the Harvard Medical School.

He is a member of the American Society of Clinical Investigation, the Association of American Physicians, the American Pediatric Society, and a Fellow of AAAS. He served on NIH Subcommittees on Biodefense and Vaccine Adjuvants; NAS panels on antibiotic resistance and academic pharmaceutical partnerships; and the ARISE 2 task force of American Academy of Arts & Science that is evaluating the impact of federal and industrial funding of science, engineering, and medicine on American universities.

Dr. Ezekowitz received his MBChB and DPhil from University of Cape Town and Oxford University, respectively. At Children's Hospital in Boston, he was a postdoctoral fellow in the Division of Hematology and Oncology with clinical training in pediatrics. He was on the staff of the Children's Hospital of Boston prior to moving to the Massachusetts General Hospital.

He is a pioneer in the field of innate immunity and has over 150 publications. In particular his group played a major role in defining the structure function of the mannose binding lectin and the macrophage mannose receptor.

Douglas A. Lauffenburger is Ford Professor of Bioengineering, and cofounder and Head of the Department of Biological Engineering at MIT, with affiliate appointment in the Department of Biology; he was a founding codirector of the MIT Computational and Systems Biology Initiative in 2002. His major research interests are in cell engineering, with central focus on cell-cell communication and intracellular signal transduction, emphasizing predictive computational models derived from quantitative experiment. Lauffenburger has coauthored a monograph entitled *Receptors: Models for Binding, Trafficking & Signaling* (Oxford University Press, 1993), has coedited the book entitled *Systems Biomedicine: Concepts and Perspectives* (Elsevier, 2010), and has supervised more than 100 doctoral and post-doctoral students. He is a member of the National Academy of Engineering and the American Academy of Arts and Sciences, and has served as President of the Biomedical Engineering Society, Chair of the AIMBE College of Fellows, and on the NIH NIGMS Advisory Council, and coauthored the NRC report on *A New Biology for the 21st Century*.

SECTION EDITORS

Kenneth E Neet received his PhD in Biochemistry in 1965 (with Dr. Frank W. Putnam) from the University of Florida. He was a postdoctoral fellow at the University of California, Berkeley (with Dr. Daniel E. Koshland, Jr.), and joined the faculty of Case Western Reserve University (CWRU) in 1967 as an Assistant Professor of Biochemistry.

Dr. Neet received a Faculty Research Award of the American Cancer Society from 1968 to 1973 and was on sabbatical leave at the National Institute for Medical Research, Mill Hill, England (with Dr. N. Michael Green) 1973–1974. From 1978 to 1990, he was Professor of Biochemistry at CWRU. During 1980–1981, he took a sabbatical year as a Josiah Macy Faculty Scholar in the Department of Neurobiology, Stanford University (with Dr. Eric M. Shooter).

Dr. Neet moved to Rosalind Franklin University of Medicine and Science/The Chicago Medical School in 1990 and was Professor and Chair of Biochemistry & Molecular Biology until 2005. Dr. Neet became Associate Dean for Research of the Chicago Medical School, RFUMS in 2004.

Dr. Neet has served on the Editorial Boards of the *Journal of Biological Chemistry*, *Protein Science*, and *Molecular & Cellular Proteomics* and as a member of study sections for the National Institutes of Health and the National Science Foundation. He was an Associate Editor of the *Journal of Biological Chemistry* (1996–2013).

Dr. Neet's research interests have been in the general areas of protein–protein interactions, allosteric interactions, protein conformational changes, and cell signaling. In his earlier years he studied theoretical and experimental aspects of slow transitions in enzymes, particularly the cooperativity of the monomeric enzyme glucokinase. Later, he studied ligand–receptor interactions of nerve growth factor, establishing a mutational system to study the interactions with its receptors (TrkA and p75), and ultimately the complex signaling emanating from these receptors within neuronal systems.

Sarah A Woodson is a biophysical chemist interested in how RNA molecules fold into specific three-dimensional structures and how they interact with proteins to turn genes on and off in the cell. She was born in Michigan, USA, and attended Kalamazoo College before receiving her PhD in Biophysical Chemistry from Yale University in 1987. After postdoctoral research in the laboratory of Tom Cech at the University of Colorado Boulder from 1987 to 1990, she joined the faculty of the University of Maryland in 1990 and the faculty of Johns Hopkins University in 1999, where she is currently the T.C. Jenkins Professor of Biophysics. Together with Mark Chance and Michael Brenowitz, she pioneered methods for visualizing how RNA molecules change shape in real time. She served on the board of the RNA Society and was elected an AAAS Fellow in 2011 and a Pew Scholar in the Biomedical Sciences in 1993. She is currently a reviewing editor of *Biopolymers* and *Journal of Molecular Biology* and serves on the editorial boards of *Nucleic Acids Research* and *RNA*.

Judith S Bond, Evan Pugh Emeritus Professor of Biochemistry and Molecular Biology at the Pennsylvania State University College of Medicine, was President of the Federation of American Societies for Experimental Biology (2012–13) and an Associate Editor of the *Journal of Biological Chemistry* (1999–2013). She received her BS degree from Bennington College in Vermont, her PhD from Rutgers University, and did postdoctoral research at Vanderbilt University. She rose through the academic ranks at the Medical College of Virginia, Virginia Commonwealth University, became Professor and Head of Biochemistry and Nutrition at Virginia Polytechnic Institute and State University, and served at Penn State University College of Medicine as Professor and Chair of Biochemistry and Molecular Biology from 1992 to 2012. At Penn State, she also served as assistant dean for graduate studies, codirector of the All-University Interdisciplinary Biological Sciences Program and founding director of the Medical Scientist Training Program. She recently directed NIH-funded summer research programs for high school students and teachers and for undergraduate students (particularly underrepresented minority groups). Her work on metalloproteases has been funded continuously by the NIH for over 35 years. She has

trained 5 Master's, 21 PhD students, and 19 postdoctoral trainees. Her professional service included member and chair National Institutes of Health Study Sections, member of the National Institute of Diabetes, Digestive and Kidney Diseases Advisory Council, member of the American Association of Medical Colleges – Howard Hughes Medical Institute Committee on the Scientific Foundations for Future Physicians, and President of the American Society for Biochemistry and Molecular Biology.

Elliot L. Elson received his AB at Harvard, his PhD at Stanford under the mentorship of R.L. Baldwin and did postdoctoral work at University of California, San Diego, under Bruno Zimm. His first independent faculty position was in the Department of Chemistry, Cornell University, where he stayed for 11 years. He then moved to the Department of Biological Chemistry (now the Department of Biochemistry and Molecular Biophysics) at Washington University in St. Louis, School of Medicine. He has pursued research in several biophysical areas. One of these is the development of Fluorescence Correlation Spectroscopy and Fluorescence Photobleaching Recovery and their application to studies of diffusion in cell membranes and of phase separation in model membrane bilayers as well as of other cellular and noncellular phenomena. He has also worked in the areas of cell mechanics, cell motility, and the mechanical properties of engineered tissues. His laboratory has developed approaches for measuring mechanical properties of cells in monolayer culture and for determining the contributions of cells and extracellular matrix to the mechanics of engineered heart and connective tissue constructs.

Tamotsu Yoshimori received his PhD degree in 1989 at Osaka University. After working at several places including European Molecular Biology Laboratory (Prof. Kai Simons' lab) and National Institute of Basic Biology (Prof. Yoshinori Ohsumi's lab), he is now a distinguished professor of Osaka University (Graduate School of Medicine and of Frontier Biosciences). His research interests are focused on intracellular membrane trafficking, and especially for the last 18 years, on autophagy. He identified LC3 as an autophagosome-binding protein, which has been widely used as the gold standard in autophagy assays. The paper has been cited over 3000 times. He also provided new insights into membrane biogenesis in autophagy and the role of autophagy in pathogen defense and suppression of various diseases. He authored or coauthored over 220 journal articles and book chapters. He is an editor of *Journal of Cell Science*, and on the editorial board of *Journal of Cell Biology*, *Molecular Biology of the Cell*, and so on. He is a member of the Faculty of 1000 and a vice president of Japan Society for Cell Biology. He was awarded Osaka University Presidential Award for 2012 and 2013, Prize for Science and Technology by the Minister of Education, Culture, Sports, Science and Technology in 2013, Kakiuchi Saburo Memorial Prize by the Japanese Biochemical Society in 2014, and selected as Highly Cited Researchers 2014 by Thomson Reuters.

Paul A. Gleeson is currently Head of the Department of Biochemistry and Molecular Biology at the University of Melbourne, located at Bio21 Institute. His research interests include the molecular mechanisms of intracellular membrane transport and the molecular basis of organ-specific autoimmune diseases. Paul Gleeson obtained his PhD in 1980 from the University of Melbourne and did postdoctoral research in the biosynthesis and function of glycoproteins at the Hospital for Sick Children, Toronto, National Institute for Medical research, Mill Hill London and Department of Biochemistry, La Trobe University, Melbourne. He established an independent laboratory at Monash University in 1986 where he defined the targeting signals of Golgi glycosyltransferases, identified golgins of the *trans*-Golgi network and along with his colleagues developed mouse models of autoimmune gastritis. In 2001 he moved to Department of Biochemistry and Molecular Biology at the University of Melbourne and has been Head of the Department since 2006. He has a number of international research collaborations and has been a visiting scientist at the EMBL, Heidelberg, and the Institut Curie, Paris.

Anna Akhmanova studied biochemistry and molecular biology at the Moscow State University. She received her PhD in 1997 at the University of Nijmegen, the Netherlands. She worked as a postdoc at the Department of Microbiology and Evolutionary Biology at the University of Nijmegen and at the Department of Cell Biology at the Erasmus Medical Center in Rotterdam, the Netherlands. In 2001, she started her own research group at the Erasmus Medical Center. Since 2011, Anna Akhmanova is professor of Cell Biology at Utrecht University, the Netherlands.

Akhmanova studies cytoskeletal organization and trafficking processes, which contribute to cell polarization, differentiation, vertebrate development, and human disease. The main focus of her studies is the microtubule cytoskeleton. Her group has described key interactions between proteins associated with microtubule ends and determined their role in the regulation of microtubule organization and dynamics. She has also characterized mechanisms of bidirectional microtubule-based motility of membrane organelles such as cell nuclei and exocytotic vesicles. Her research relies on combining high-resolution live cell imaging and quantitative analysis of cytoskeletal remodeling, measurement of protein dy-

namics using advanced microscopic assays, *in vitro* reconstitution of dynamic cytoskeleton-based processes and different methods of identification of protein–protein interactions.

Anna Akhmanova is a recipient of the ALW Vernieuwingsimpuls VIDI (2001) and VICI awards (2007) (Netherlands Organization for Scientific Research), and an ERC Synergy grant (2013). She is the Chair of the board of the Netherlands Microscopy Society and a member of the European Molecular Biology Organization (EMBO).

Yosef (Yossi) Yarden is a Professor in the Department of Biological Regulation at Weizmann Institute of Science (Rehovot, Israel). Dr. Yarden obtained his PhD from Weizmann Institute (under the mentoring of Dr. Joseph Schlessinger) and later trained at both Genentech Inc., with Dr. Axel Ullrich, and at the Whitehead Institute (MIT), with Dr. Robert A. Weinberg. His group studies the roles played by growth factors and their receptors in cancer progression. They also explore strategies able to intercept growth factor signals in tumors.

Jason D Weber is an Associate Professor in the Departments of Internal Medicine and Cell Biology and Physiology at Washington University and is the Coleader of the Breast Cancer Research Program in the Siteman Comprehensive Cancer Center. Dr. Weber obtained his PhD from Saint Louis University and received postdoctoral training under the mentoring of Dr. Charles J. Sherr at St. Jude Children's Research Hospital in Memphis, TN. His group studies the molecular interplay between oncogenes and tumor suppressors, particularly focused on their role in regulating cellular growth processes.

Michael Dustin received his PhD in 1990 in Cell and Developmental Biology from Harvard University, where he worked in the laboratory of Timothy A. Springer, PhD. During his graduate work he was involved in the identification and cloning of ICAM-1 and ICAM-2, key ligands for the integrin LFA-1. He further demonstrated that LFA-1 dependent adhesion was stimulated by T cell receptor signaling. He did his postdoctoral training with Stuart Kornfeld at Washington University School of Medicine in St. Louis, focusing on mechanisms of lysosome biogenesis. He started his independent lab also at Washington University School of Medicine, and used supported lipid bilayers to define the first protein to modulate organization of the immunological synapse- CD2 associated protein- and the dynamics of immunological synapse formation. He moved to NYU School of Medicine in 2001 where he applied *in vivo* microscopy to tolerance induction and immune responses in effector sites including the liver, brain, and spleen. Continued work with the immunological synapse model resulted in discovery of signaling microclusters, the molecular basis of immunological synapse stability, and the direct budding of extracellular microvesicle enriched in T cell receptors in the immunological synapse. Professor Dustin recently took a position at the

University of Oxford with support of a Wellcome Trust Principal Research Fellowship. The focus of his new post is the translation of the immunological synapse. He received a Presidential Early Career Award in Science and Engineering and the DART-NYU Biotechnology Achievement Award.

David A Sassoon directs a research team at Paris Sorbonne. He received his PhD from Columbia University (NYC, USA) in 1986 in the biological sciences and was a professor at Boston University Medical School and Mt. Sinai Medical School before relocating to Paris in 2006. His long-standing interests are in developmental and stem cell biology in a number of tissues including skeletal muscle, skin, CNS, and heart. Dr. Sassoon recently concluded the coordination of a EC-funded 15 partner international consortium (Endostem) designed to identify novel therapeutics for mobilizing endogenous stem/progenitor cells (<http://www.endostem.eu/>) and is a recent recipient as coordinator of a multipartner Transatlantic Network of Excellence grant from the Fondation Leducq focused on cardiac stem cell biology (<http://www.fondationleducq.org/nivel2.aspx?idsec=1360>).

A major focus of his research is on adult progenitor/stem cell biology and how these cells respond to stress. His team has identified a parentally imprinted gene, PW1/Peg3, which is involved in both p53 and inflammatory responses. PW1 is expressed in adult stem cells in all tissues identified to date. Loss of PW1 function in stem cells results in a loss of stem cell competence including a reduced capacity to undergo self-renewal and respond to hypoxic stress. We are currently evaluating a role for PW1 in postnatal and adult heart with a particular focus on its role in vessel precursors using both myocardial infarction and stress-induced myocardial hypertrophy.

Jason M Haugh is a Professor of Chemical and Biomolecular Engineering at North Carolina State University in Raleigh, NC, USA, where he has been on the faculty since 2000. His laboratory has been among those to pioneer the synthesis of quantitative experiments and modeling to study signal transduction in mammalian cells. Since the lab's inception, their approach has combined biochemical measurements, live-cell fluorescence microscopy, and computational modeling to elucidate signaling mechanisms by analyzing their kinetics and spatial organization in cells. The systems studied by the Haugh Laboratory include: regulation of the phosphoinositide 3-kinase, Ras/extracellular signal-regulated kinase, and phospholipase C pathways mediated by receptor tyrosine kinases, and cross talk between these pathways; dynamic organization of multimolecular complexes at cell membranes; signaling mediated by cytokine and chemokine receptors in immune cells; and integration of adhesion, signaling, and cytoskeletal dynamics that direct cell migration.

After graduating with an MA in Mathematics from the University of Cambridge, Helen Mary Byrne received her Master of Science and DPhil from the University of Oxford. She worked as a postdoctoral researcher at the Universities of Oxford and Bath, before taking up a lectureship at the UMIST in Manchester. She moved to the University of Nottingham in 1998 and was awarded a prestigious Advanced Research Fellowship from the United Kingdom's Engineering and Physical Sciences Research Council (2000–2006). She was promoted to Reader in 2002 and Professor in 2003. While in Nottingham, she established and then led the Centre for Mathematical Medicine and Biology until she returned to Oxford in 2011 where she is now based in the Mathematical Institute at the University of Oxford. She has over 20 years' experience of developing, analyzing, and simulating continuum and multiscale models of biomedical systems, and a particular interest in studying the growth and response to treatment of solid tumors.

Rune Linding completed his PhD at the European Molecular Biology Laboratory (EMBL) in Heidelberg, Germany, followed by postdoctoral training at EMBL. He then jointly trained with professors Tony Pawson and Mike Yaffe at the Lunenfeld at Mount Sinai Hospital in Toronto, Canada, and the Massachusetts Institute of Technology (MIT) in Cambridge, US, respectively. Dr. Linding then established his own laboratory of Cellular and Molecular Logic at the Institute of Cancer Research (ICR) in London, UK, before returning to Denmark to take a position as professor of cellular signal integration at the Technical University of Denmark. In 2014, Dr. Linding moved his laboratory to the Biotech Research and Innovation Centre (BRIC) at University of Copenhagen where he is currently professor of cellular signaling. His research group focuses on big data network biology, exploring biological systems by developing and deploying algorithms aimed to predict cell behavior, in particular looking at cellular signal processing and decision making. A strategic focus is to continue to develop computational tools (such as KinomeExplorer, NetworKIN, and NetPhorest) and to deploy these on genome-scale quantitative data obtained by, for example, mass spectrometry, genomic, and phenotypic screens to understand the principles of how spatio and temporal assembly of mammalian signaling networks transmit and process information at a systems level in order to alter cell behavior. His overarching aim is to advance network

medicine by identifying and targeting signaling networks associated with complex diseases. To this end Dr. Linding is currently leading high-level, strategic, multidisciplinary studies of signaling network dynamics driving cancer metastasis in collaboration with other labs at Harvard, Yale, The Jackson Laboratory, Memorial Sloan Kettering Cancer Center, MIT, and BRIC.

PREFACE

Cell biology is the study of cells, the integral unit that is the basis of all living tissues. In its earliest phases, this area of investigation was largely defined by microscopic-based observations of structure and organization that were, by their nature, largely descriptive. This also served to delineate cell biology from its nearest neighbor, biochemistry, which, dating from its post WWII renaissance, was driven in large part by reductionist approaches, where tissues, cells, and organelles were broken down in order to isolate and then characterize individual components. The melding force that bridged these two areas was molecular biology that allowed the cell biologist to transform pictures into functions and allowed the biochemist to reassemble their components into ensembles and subcellular entities. Not surprisingly the boundary between these two key biological sciences has become blurred beyond recognition. Today a considerable part of what passes as cell biology is by any other name biochemistry (or molecular biology – the distinction between these two areas being equally indistinct) and vice versa. Indeed, one of the first challenges we faced in organizing this Encyclopedia was how much molecular detail to include. It was our conclusion that for the sake of completeness, and to appropriately introduce the volumes Organizational Cell Biology and Functional Cell Biology, we needed a description of the molecular components of the cell, particularly with respect to the synthesis and degradation of proteins and nucleic acids, along with outlines of important chemical principles and key methodology. We were guided to some degree in these decisions by input from undergraduate and graduate teachers and the contents of their introductory courses that they shared with us and by discussions with our volume and section editors. The result was the first volume which we recognize is very 'biochemical,' but certainly lacking the more detailed coverage of the *Encyclopedia of Biological Chemistry* (Lennarz and Lane, 2004) or the many excellent biochemical texts that dot the educational landscape. Readers who find 'gaps' or incomplete treatments in this section will likely be able to find the additional detail they seek from these sources.

The second major decision that we had to confront was whether we would attempt to cover the full range of living organisms or whether we would place some limits on the scope of the material we included. In the final result, it was decided to place the emphasis on higher eukaryotes with only very prescribed treatments of lower eukaryotes and prokaryotes. Volumes 2 and 3 thus deal with material that has perhaps been more traditionally thought of as cell biology. Again we were guided in our decisions about what to include by teaching considerations, brainstorming sessions with our editors, and a perceived need to separate cellular organization from cellular function. However, as even a quick perusal will reveal, this is not a sharp delineation either. Volume 2 begins with a methodological treatment of imaging, which is basically divided between light and electron microscopic applications, and is followed by sections on organelles, interorganellar communication, and the cytoskeleton (including motors). The

last part of volume 2 is devoted to intracellular infection and covers a variety of external agents and pathogens that impact cell function as well as human pathology. Volume 3, in contrast, largely deals with major cell functions: signaling, cell-cycle control, and apoptosis. The last two parts are devoted to cells of the immune system and their responses and stem cells – two highly specialized niches characterized by unique cellular involvement.

The last part of the Encyclopedia deals with systems biology. This is really the newest area of cell biology and considers cellular involvement as part of a phenotypic response. As such, it strives to integrate all of the levels of the first three volumes in a consistent manner to produce a seamless description of cellular function. This is clearly a newly evolving area and the most rapidly changing part of cell biology; indeed it is where we expect to see the greatest change in the next few years.

Assembling a treatment of a topic as large as cell biology had multiple challenges. Coverage was a significant problem: on the one hand it was almost impossible to avoid some redundancy in places while, on the other, there were inevitable gaps. Some of these arose from late cancellations; others from oversights on our part. We can only promise to fill these in future editions. We also note that as can be expected for a large multiauthor compilation the individual articles do differ in detail and treatment. We felt it was more important to allow our experts substantial latitude in deciding how to present their topics than to apply rigid guidelines. We did try to limit the number of references (to make it easier for people not familiar with a topic to make the transition to more extensive articles) but there is admittedly some considerable variation in the bibliographic material as well.

When we were well into the project, we were approached by Graham Nisbet (Elsevier) about including the Encyclopedia in a larger collection entitled the Reference Module in Biomedical Sciences. The Reference Module plan was grouped in single integrated work information from several other compendia and it was our view that this would greatly leverage the value of our efforts (and those of our contributors). While we were the 'new kid on the block' in that we were still compiling the Encyclopedia and the other collections to be included were already extant, we felt that it was too good an opportunity to pass up. The Reference Module has since been launched and although it does not yet contain the complete content from the Encyclopedia, this will be achieved in the not too distant future. We consider that this will be a particularly valuable resource for researchers that are just entering (or changing into) this field.

No work of this size could be completed without the help and advice of many people. In this regard we would like to thank a number of people who were instrumental in bringing this project to fruition. First and foremost we would like to recognize our volume editors: Jerry Hart, Graça Raposo, Bruno Goud, Alan Ezekowitz, and Doug Lauffenburger; and our section editors: Ken Neet, Sarah Woodson, Judy Bond,

Elliot Elson, Tamotsu Yoshimori, Paul Gleeson, Anna Akhmanova, Yosef Yarden, Jason Weber, Michael Dustin, David Sassoon, Jason Haugh, Helen Byrne, and Rune Linding; and thank them for their invaluable input, enthusiasm, and hard work. They are truly a global group and have been a great team to work with. We also wish to thank the staff at Elsevier including Janice Audet, Peter Labella, Nicky Carter, Karen Maloney, Erin Hill-Parks, Rashmi Phadnis, Blerina Osmanaj, and Ginny Mills for their many efforts, perseverance (particularly with our idiosyncrasies), and skillful management of every aspect of this project.

In the course of planning this work, we gathered information from a number of sources. At the outset the publishers polled some 167 faculty from both undergraduate and graduate schools to ascertain their perceived interest in such a project, which also garnered considerable input about potential topics. The response was highly favorable. We also talked with many colleagues about experiences at their institutions and would like to particularly thank Catherine Bevier (Colby College), Robert Simoni (Stanford University), Larry Marsh (UC Irvine), and John Cooper (Washington University) for providing syllabi of germane courses taught in their institutions. Special thanks also go to Ruedi Abersold (ETH, Zurich) and Sergio Grinstein (University of Toronto) for their expertise that they readily shared with us, which was invaluable in planning certain sections.

Finally we would like to recognize all of our authors. We have been extraordinarily fortunate in attracting individuals from all around the globe to take time from their busy schedules to prepare this splendid set of contributions. Without these efforts there would be no Encyclopedia. Under ordinary circumstances it would be appropriate to dedicate the work to them and all the colleagues whose works they wrote about. However, during the preparation of this work, we sadly lost one of the most important contributors to cell biology, Tony Pawson. Tony was a true pioneer in elucidating basic mechanisms of how cells transmit information intracellularly, a fundamental knowledge that permeates all of cell biology. In an effort that was initiated by one of the section editors, Rune Linding, it was decided to dedicate the entire work to his memory as recognition of his contributions and a lasting tribute to a man who left us too soon.

We hope that the Encyclopedia will be of value to students and researchers alike and will become a useful tool in the training of future generations of scientists.

Ralph A Bradshaw and Philip D Stahl

All living organisms can be divided into three principal categories: archaeobacteria, eubacteria, and eukaryotes; although they differ in structure and organization, they are all composed of cells as the fundamental life unit. At the molecular level, there is also a great deal of similarity in the basic materials that make up these entities because they use the same kinds of molecules to store and reproduce information, to run the cellular metabolism and machinery and to provide the structural framework. Thus nucleic acids, proteins, lipid membranes, and carbohydrates – alone and in various combinations – are universally present, albeit in distinguishable forms, along with innumerable metabolites and ions. There are components that are apparently essential for life and are found in one form or another in all species and there are many unique moieties and associated activities that are highly specialized and are found in relatively few organisms. Indeed, the similarities have underpinned the development of our understanding of cellular function at a rudimentary level and the differences, basically engendered by evolution, have illustrated and delineated the complexity that speciation has introduced. Perhaps the largest of these differences is that which separates single cell organisms from multicellular organisms. The latter are exclusively eukaryotes while the former are composed of both eukaryotes and prokaryotes. The cellular organization and architecture that distinguishes these two major life forms is striking; although cell biology correctly embraces both, traditionally prokaryotic organisms have been the province of the microbiologists and the majority of cell biology research has been devoted to the eukaryotic world. In practical terms this translates for the most part into the study of human cells and those of easily maintained laboratory animals and selected paradigms, for example, fruit flies, worms, and zebra fish.

Human and animal cell biology is not a tightly proscribed science with well-defined borders. Basically it serves at the interface between biochemistry, molecular biology, and genetics, on the one hand, and anatomy and physiology, on the other. The continuum of these disciplines forms the core of the biomedical sciences, which also include the related but separate fields of pharmacology, microbiology, immunology, and pathology that provide the connections to disease and health. Cell biology has strong connections to all of these. There are also specialized areas, for example, neuroscience, that are of such importance that they warrant their own category and the cell biology associated with them is also highly specialized. Thus, cell biology is as complex as the enormous variety of cells that exist and achieving an accurate description of all of them in terms of their components and functions has long been a major part of the research in this field.

Imaging and Organelle Organization

Among the developments that propelled cell biology into the modern era are the introduction of the ultracentrifuge and

the rapid advances in microscopy both electron and light microscopy – the former allowing investigators to fractionate and characterize the components of the cell and the latter to literally see them – either *in situ* or in isolated form. This progress is illustrated by a series of Nobel Prizes starting in the early 1970s that chronicle the grand confluence of classical biochemistry and general physiology that created modern cell biology (Claude *et al.*, 1974) or the discovery and characterization of intracellular organelles – lysosomes and endoplasmic reticulum (ER) among others (Mitchell, 1978), for the chemiosmotic hypothesis (Brown and Goldstein, 1985), for endocytosis (Ciechanover *et al.*, 2004), for ubiquitination and protein degradation, and just recently (Rothman *et al.*, 2013), for vesicle trafficking, and (Betzig *et al.*, 2014) for advances in light microscopy. The early cell biologists insisted on quantitative application of these new techniques and laid the groundwork for modern cell biology. As with biochemistry, reductionism has been the keystone for the amazing success over these past several decades. Each organelle has its own research history – the nucleus, mitochondria, peroxisomes, the proteasome, the ER, and cytoskeleton. The Golgi apparatus/secretory pathway and the endosome–lysosome network have all been examined in detail both in isolation and in their relationships with each other. A new member, the exosome (aka extracellular vesicle) has emerged more recently and stimulated the imagination of aspiring young investigators (Harding *et al.*, 2013). The rise of genomics, the development of spectacular imaging modalities, and evolving biochemical techniques (proteomics) have led to the discovery of molecular motors, the identification of macromolecular complexes such as the exocyst, ESCRT, GARP, SNAREs among others that choreograph complex intracellular pathways, including cell motility and cytokinesis, have brought cell biology into this new era where the whole is now seen as larger than the individual components. This creates the segue from Parts 1 and 2 of the *Encyclopedia (Molecular Cell Biology and Organizational Cell Biology)* to Part 3 (*Functional Cell Biology*) where signaling modalities will be seen as an integrative force for regulation and control.

Signaling

While all organisms can sense their environment and respond to cues from it, multicellular organisms must in addition coordinate their responses, which require intercellular communication at a sophisticated level (Bradshaw and Dennis, 2009). The higher the development, the more complex these communication systems become. Thus the cell biologist must focus not only on how molecular function is translated into cell organization and how these functions are coordinated from organelle to organelle but also on the external interactions and signals that control the larger functional responses of organs and ultimately organisms.

Intercellular communication is afforded by stimuli that can be transmitted across the cell membrane, either directly or via membrane bound molecules that in turn pass signals to the intracellular compartment. The origins of these stimuli may be quite diverse. Among other things, they can include cell–cell contacts, soluble factors/messengers, or foreign agents. Lipophilic molecules can cross the membrane by diffusion or by facilitated transport to recognize and bind to intracellular entities but most substances bind to membrane bound proteins and induce their signal by ‘activating’ them instead. These so-called receptors are capable of producing a variety of responses that invariably involve the generation of posttranslational modifications of preexisting proteins. Protein phosphorylation, which in eukaryotes mostly occurs on tyrosine, serine, and threonine residues, is highly prevalent and appears to be directly or indirectly involved in almost all transmembrane signaling (Gnad *et al.*, 2011). However, it is by no means the only vehicle for transmitting information as acetylation, methylation, monoglycosylation, and ubiquitination, to name a few, are both important and widespread. There are over three hundred different covalent modifications (Khoury *et al.*, 2011) that are introduced into proteins (and many more that have not yet been chemically defined) of both a transient and stable nature and most are likely to be involved to some extent in signal transduction processes. In addition, limited proteolysis can also be an important part of a pathway and this activity is a major player in cellular responses (Turk *et al.*, 2012).

The induction of an intracellular signal is basically perpetrated by the formation of new interactions between the modified proteins and other entities, which can range from small molecules to macromolecular protein complexes. One of the most important advances in understanding how cells process information induced from external stimuli was the appreciation that the newly formed sites produced by the protein modifications were recognized by other proteins with modules specifically designed for this purpose (Pawson, 1995). Thus, for example, phosphotyrosine residues could be recognized by other proteins containing a domain, termed SH2 for its relatedness to a similar domain found in the Src protein kinase, which could then be further modified allowing for additional interactions to occur. By these ‘docking’ events, signaling complexes could be assembled, often in multiple steps, that ultimately lead to the activation of key effectors. The end point of many of the pathways is the activation of transcription factors that lead to the modulation of gene expression of that cell by ultimately changing its protein expression profile (Bradshaw and Dennis, 2009). However, many molecules are usually modified and activated ‘along the way’ and these ‘new’ activities also add to the overall response to the original stimuli. Short term responses indeed require that the protein effectors necessary for it are already present; long term responses per force require new protein synthesis.

Signal transduction is thus dependent on two phenomena: posttranslational modifications, particularly of the readily reversible type, and protein–protein interactions. The extent to which these two activities take place, even in resting, unstimulated cells was greatly underestimated before the advent of proteomics and the introduction of mass spectrometric methodology into cell biological research (Bradshaw and

Burlingame, 2005) These high-throughput unbiased analyses of very complex mixtures, basically derived directly from cell lysates, revealed that essentially every protein had multiple interacting partners and that posttranslational modifications affected a very significant proportion of the proteins present. These were profound differences from what had been the prevailing wisdom and amounted to a paradigm shift in thinking about cellular organization and structure. As noted above, these same tools have gone on to cast new light on organelle organization in terms of resident proteins and have helped to disclose the structure of important cellular machines, such as the proteasome (Voges *et al.*, 1999), the nuclear pore (Routa *et al.*, 2000), and transcription complexes (Kornberg, 2007). They have also begun to elucidate the complexity of epigenetic regulation of gene transcription at the histone level (Cosgrove, 2012), which will also be essential in completing our understanding of signaling processes.

Concluding Remarks

Two of the most fundamental aspects of cells are their ability to reproduce themselves and, in higher organisms, to undergo changes that lead to new cell types and functions. These developmental processes leading to differentiation are what allow a single fertilized egg to form a complex adult organism and require the synthesis of all aspects of cell biology to understand. Knowing how cells go from one state to another in a timed and regulated fashion forms the core of developmental biology, which can be viewed as a sub discipline of cell biology. Also of major importance is the maintenance of viability and the associated turnover processes. The control of cell death is not only an essential part of development it is also key to managing situations that have gone awry and underlies many serious disease conditions.

It is clear that science is still a long way from understanding how even simple cells work. There is a long list of functions and structures that remain to be elucidated and integrating the various experimental approaches and the data they produce still lags far behind. This is the ‘Era of Big Data’ and vast amounts of new information that impact on our understanding of cells and their processes are collected every day. Genomic information is a good example – despite the rapidity that this sort of information can now be obtained, it still remains to be effectively mined in terms of what it can tell us about basic principles of how cells work. There has been an understandable pressure to apply this information to managing disease (Collins and Varmus, 2015), particularly those that are life threatening, but there certainly is information that is yet to be formulated that would apply to fundamental problems as well. The same can be said for transcriptomics, proteomics, and metabolomics. In addition to these powerful new technologies, singular advances in analyzing single cells promises to augment these molecular approaches significantly (Di Palma and Bodenmiller, 2015).

One aspect of cell biology that is looking to address the challenges of integrating these relatively newly minted studies is systems biology (Part 4). It is far too early to assess the value of these efforts in coordinating this flood of information but it certainly looks promising. It will be an elusive goal for some

time to come but also a stimulus for new generations of cell biologists that will be forthcoming.

Introduction

This section of the Encyclopedia addresses fundamental questions as they pertain to the physiology of cellular homeostasis. Basic questions about the regulation of cell growth and cell content are discussed. How transformation of cells is a result of misdirected homeostasis that affects selected cellular functions and diverts others. This intrinsic threat is contrasted to external threats posed by infectious agents that rouse the innate immune system, which in turn alerts the adaptive immune system, if required. Host defense might disrupt tissue continuity and function. How and when repair can evoke regeneration of tissue is discussed in the section on stem cell biology. The narratives underscore an elegant complexity that underlies the preservation of health and provides insights into the mechanism of disease.

Cell Signaling and Intercellular Communication

When unicellular creatures first assembled to generate the cooperatives we now call multicellular organisms, they inevitably handed over the lion share of their autonomy. The new biochemical 'language' that had concomitantly evolved confers to metazoans an amazingly complex and busy intercellular communication. This communication is crucial for benefitting the synergy offered by many collective cellular effects, which constantly establish sophisticated organs and whole-body systems, such as the immune system. Understanding the linguistic nuances of cell-to-cell interactions is not only interesting and informative but also very useful, for many diseases are rooted in miscommunication and unauthorized autonomy. This part of the *Encyclopedia of Cell Biology* teaches and exemplifies the vocabulary of intercellular communication. The 'receptors' receive special attention; several families of these molecular devices exist in mammals and they all come with two faces: the extracellular face receives a cue, in most cases a molecule carrying a physiological message, such as a growth factor. The receptor's part facing the cytoplasm instigates a biochemical pathway (a.k.a., signal transduction), variably mediated by posttranslational protein modifications, elevation of second messenger molecules (e.g., cyclic adenosine monophosphate or calcium ions), or formation of new protein complexes. Unlike the multiple extracellular cues and their many receptors, only a few 'signal transduction pathways' exist in eukaryotic cells. And while the principal pathways are reviewed in this part, it is becoming increasingly clearer that several pathways are simultaneously activated by each receptor. The identity and relative strength of such pathway combinations are decoded intracellularly by the transcriptional

machinery, adhesive properties of the cell surface, the endocytic pathway, and other 'cellular machineries,' as exemplified by several articles. To demonstrate 'cellular outcomes' of the enormous complexity of intercellular communication and the associated clinical implications, this part culminates by highlighting wound healing, colonization of distant organs by cancer cells (metastasis), and neural repair mechanisms.

Receptors

Intercellular communication may be likened to a large funnel: multiple polypeptide and other messengers, in the form of cytokines and growth factors, mediate cellular interactions by binding to several receptors, each able to bind with a few ligands and couple their biochemical messages to still fewer cytoplasmic signaling pathways. Accordingly, the cell surface receptors, which fall into a few families and subfamilies, carry out a critical function as translators of extracellular cues into intracellular signals. One important family, receptor tyrosine kinases (RTKs; see [Receptor Tyrosine Kinases and Their Ligands](#)), comprises 58 members and 20 subfamilies. Ligand binding promotes dimerization of RTKs, which causes activation of their kinases and autophosphorylation, thereby providing docking sites for downstream signaling molecules with phosphotyrosine binding specificity (e.g., SH2 domains). Several hormones, interleukins, interferons, and colony stimulating factors bind with other transmembrane receptors, which lack an intrinsic tyrosine kinase function and belong to the cytokine receptor family (see [Cytokine Receptors and Their Ligands](#)). Like the RTKs, receptors for the transforming growth factor beta (TGF- β) family of ligands harbor protein kinase activity, albeit with specificity to residues other than tyrosine, and they transmit signals through a dedicated group of adaptors (see [TGF- \$\beta\$ Superfamily Signaling](#)). Unlike the above-listed single-pass receptors, the largest family of receptors, G protein-coupled receptors (GPCRs), includes molecules that transverse the plasma membrane seven times (see [G Protein-Coupled Receptors](#)). GPCRs generate intracellular second messengers and also engage intracellular signaling pathways (through arrestins). Two additional, smaller groups of receptors, guanylyl cyclase receptors (see [Guanylyl Cyclase Receptors](#)) and receptors for tumor necrosis factors (TNFs; see [Tumor Necrosis Factor Receptors: A Brief Digestion](#)), are also described.

The Signal Transduction Pathways

Although it is already clear that cascades of proteins engaged by each type of ligand-occupied receptors often bifurcate and channel their signal laterally and even backward, these

pathways are commonly described as linear and unidirectional. Perhaps the best understood pathways are those recruited, by means of adaptor proteins containing SH2 or SH3 domains (see [SH3 and SH2: Prototypic Domains to Mediate Regulatory Mechanisms in the Cell](#)), to ligand-activated RTKs and cytokine receptors. These are the mitogen-activated protein kinase (MAPK) route (see [The MAPK Signaling Cascades](#)), the PI3K-AKT-mTOR pathway (see [The PI3K/Akt/mTOR Pathway](#)), the JAK-STAT (see [The JAK-STAT-SOCS Signaling Cascade](#)), the phospholipase C (PLC) to protein kinase C (PKC) (see [The PLC Pathway](#)) cascade and the calcium-calmodulin pathway (see [Calcium and Calmodulin Signaling](#)). Because several signaling pathways regulate bidirectional transport of proteins between the cytoplasm and nucleus, which occurs through nuclear pores, this rather common aspect is also reviewed (see [Macromolecular Communication between Nucleus and Cytoplasm](#)). Additional, more restricted pathways, include sonic hedgehog (SHH), which enables morphogens to pattern tissues such as the neural tube and limb bud by regulating processing of master transcription factors (see [Hedgehog Signaling in Development and Disease](#)). The Hippo signaling pathway similarly regulates organ size and tissue regeneration by means of a kinase cascade and retention of a complex of two transcription repressors in the cytoplasm (see [The Hippo Pathway](#)). As befits its many roles in tissue homeostasis, the Hippo pathway interacts with other signaling players, such as the Notch and WNT pathways. In mammals the Notch pathway consists of four receptors and five ligands (see [The Notch Pathway](#)). These ligands, expressed on the surface of a signal-sending cell, bind to and activate Notch receptors on neighboring cells. Ligand binding instigates receptor cleavage followed by translocation of the intracellular domain of Notch to the nucleus and formation of an activating complex that up-regulates target gene expression. In analogy, a major effector of the canonical WNT signaling pathway is the transcription factor β -catenin (see [The Wnt \$\beta\$ -Catenin Pathway](#)). In the absence of ligand, β -catenin interacts with two scaffold proteins and is a substrate for two kinases. Phosphorylated β -catenin is then ubiquitinated and destroyed. When WNT ligand binds to a Frizzled family receptor, the multiple component destruction complex is inhibited, leading to the stabilization of β -catenin and its translocation to the nucleus, where it interacts with TCF/LEF family transcription factors, so target gene expression is activated. In contrast to the WNT, Hippo, and Notch pathways, which culminate in transcription regulation, signaling downstream of death receptors, like TNF-receptors, initiates programmed cell death by means of activating multiple cytoplasmic proteases of the caspase family (see [Signaling and Function of Death Receptors of the Tumor Necrosis Factor Receptor Superfamily](#)).

Cellular Machineries

One cellular machinery that both regulates signal transduction and is profoundly regulated by intracellular signals is endocytosis of both surface proteins and extracellular, soluble molecules (see [Endocytosis of Cargo Proteins: LDL in Part 2](#)). Although the selection of cargo is wide, the principles

underlying endocytosis are quite common. The article included herein describes how cholesterol circulates in the form of low-density lipoprotein (LDL) particles, which must be internalized to enable entry into cellular membrane pools. On its own, endocytosis regulates cell polarity, which is vital to the function of specialized cells of the epithelium, immune, and nervous systems (see [Regulation of Cell Polarity](#)). Endocytosis regulates yet another machinery, which ensures cell-cell adhesion and employs diverse types of intercellular junctions, including cadherin-based junctions (see [The Molecular Architecture of Cell-Cell Adhesions](#)). The related machinery, namely cell adhesion to extracellular matrices, involves specific bonds between membrane proteins and their extracellular ligands (see [Extracellular Regulation of Cell-to-Matrix Adhesion](#)). This type of cell adhesion is altered by changes in the chemical or physical properties of the matrix, which critically affect normal development and pathology. How cellular machineries, such as adhesion, endocytosis, and cytoskeletal reorganization, are functionally integrated is well exemplified by cellular motility (see [Regulation of Cell Migration](#)). This process is heavily regulated at multiple steps of the migratory process, to enable control of development, wound healing, and immunity.

Cellular Outcomes

The impact of cell-to-cell communication on pathology is herein exemplified by the process that heals skin wounds (see [Wound Healing: An Orchestrated Process of Cell Cycle, Adhesion, and Signaling](#)). Stepwise blood clotting and inflammation, new tissue formation and, eventually, a long tissue remodeling process, engage many signaling pathways and some of the above-described cellular machineries. Even more life threatening and widely spread in the body is the metastatic process, in which cancer cells disseminate from their primary sites to form secondary tumors throughout the body (see [Cancer Cell Invasion through Tissue Barriers](#)). The initial step of tumor cell dissemination is followed by invasion into the surrounding tissue, subsequent intravasation into the circulatory system and, finally, extravasation at a distant site to instigate organ colonization. Intercellular communication between highly specialized cells, such as neurons, requires very long axonal processes connecting neurons to their targets (see [Neuronal Transport and Spatial Signaling Mechanisms in Neural Repair](#)). Injury of axons disrupts this intercellular communication, such that neural function can only be restored by regeneration of axons and their target reinnervation. Regeneration requires growth factors, receptors, intracellular trafficking of molecules, and organelles, as well as components of the neuronal cytoskeleton, all supporting growth of the injured axon.

Cell Growth

One of the outstanding fundamental questions in cell biology concerns how cells coordinate cellular growth (or macromolecular synthesis) with cell cycle progression and mitosis. Intuitively, rapidly dividing cells must have some control over these processes; if not, cell would continue to shrink in volume

with every passing cycle, similar to the cytoreductive divisions seen in the very early stages of embryogenesis. The problem is more easily solved in unicellular organisms, such as yeast, as their growth rates are entirely dependent on nutrient availability. Multicellular organisms must have acquired additional levels of control, as nutrient availability is seldom an issue and the organism has a prodigious capacity to store necessary metabolites in the form of glycogen, lipids, and protein. While myriad mechanisms of preventing unrestricted cellular proliferation exist via initiating programmed cell death (e.g., apoptosis, autophagy, necrosis), these mechanisms all depend on some external cue like those emanating from hypoxia, death signaling ligands, and lack of nutrients or survival signals. In the following articles, we will introduce the principle processes involved in cellular growth and macromolecular synthesis. Subsequent articles will then clarify the contrasting conditions of cell death and cell cycle progression and how cells are poised to choose between these two states in order to grow or die.

Ribosome Biogenesis Pathways

An essential feature of cell growth regulation is the tight coupling between ribosome synthesis and extracellular conditions. Although macromolecular synthesis is distinct from cell cycle progression and division, the two processes are coordinated. Cell mass and DNA content both double during each cell division, thus ensuring that cells remain a constant size under proliferative conditions. In yeast and mammalian systems target of rapamycin (TOR) is a key regulator of these two processes, providing the bridge between growth and proliferation. TOR was first identified by genetic screens in yeast aimed at identifying the protein TOR, a potent immunosuppressive macrolide produced by *Streptomyces hygroscopicus*. The mechanism of action for rapamycin is conserved in eukaryotes, with single TOR orthologs identified in *Caenorhabditis elegans*, *Drosophila melanogaster*, and mammals, and will be discussed in the first article of this section (see [mTORC1: Upstream and Downstream](#)).

In recent years, it has become apparent that a major function of TOR is to connect incoming environmental signals to ribosome production. It is estimated that approximately 50% of the cell's energy expenditure is directed toward ribosomal biogenesis. Given these costly energy projections, the cell has adopted stringent criteria that must be met before engaging the ribosome biogenesis machinery. As such, TOR is able to link these criteria to the cellular home of ribosome biogenesis, the nucleolus (see [The Nucleolus](#)). The nucleolus, long recognized as a marker for active cell growth, was first described as the center of ribosomal biogenesis and rDNA transcription in the early 1960s. This membrane-free organelle is composed of three regions on the basis of morphology at the ultrastructural level as well as the function of each distinct region. The nucleolus is sensitive to both positive and negative regulators of growth: ribosomal proteins themselves can act as signaling proteins often operating as communicators of stress to alter cell growth patterns in mammals (see [Ribosomes and Stress – Linked from Birth to Death](#)). Intriguingly, ribosomal proteins themselves may function as bona fide tumor suppressors. It is

well appreciated that ribosomal proteins possess extra-ribosomal functions in DNA damage responses and cell cycle regulation. Recently, several ribosomal proteins were found to antagonize the MDM2 oncogene, causing an induction of a p53-dependent cell cycle arrest. Thus, perturbations of ribosomal biogenesis or nucleolar architecture may lead to release of ribosomal proteins into the nucleoplasm where they might act in non-ribosome capacities (see [Extra-Ribosome Functions of Ribosomal Proteins](#)).

Ribosomal biogenesis begins with the Pol I-dependent transcription of the tandemly repeated rDNA loci on the five acrocentric chromosomes in humans. The product of Pol I transcription is the 47S pre-rRNA which, much like its mRNA counterparts, must be properly processed to yield functional rRNA and subsequent ribosomes (see [Ribosomal RNA Processing](#)). This consists of a series of base modifications (pseudouridylation and 2'-O-methylation) followed by an ordered cleavage by processing RNases to yield the 28S, 18S, and 5.8S rRNA species. Mature eukaryotic ribosomes have a small 40S and large 60S subunit, both of which are assembled within the nucleolus and exported into the cytoplasm. The large subunits are composed of the 28S, 5.8S, and 5S (made in the nucleoplasm) rRNAs plus large associated ribosomal proteins (e.g., L5, L7, etc.) while the small subunits contain the 18S rRNA and small ribosomal proteins (e.g., S3, S6, etc.). In all, these four rRNAs must assemble with more than 70 ribosomal proteins to undergo a series of maturation steps before gaining full functionality (see [Eukaryotic Ribosome Assembly and Export](#)).

Translation

Regulation of translation functions as an important biological mode to modulate gene and protein expression. The translational process can be separated into three phases: (1) initiation, (2) elongation, and (3) termination. While a limited number of factors are involved in elongation and termination, numerous protein-mRNA and protein-protein interactions are necessary for proper initiation. Indeed, more than 25 proteins have been implicated in eukaryotic initiation and at least 11 initiation factors are necessary for proper translation initiation. Thus, it is not surprising that initiation appears to be the rate-limiting step in translation for nearly all eukaryotic mRNAs. As such, translation initiation is the most frequent target of translational regulation. The majority of eukaryotic mRNAs are capped at their 5' ends by a 7-methyl guanosine moiety. A heterotrimeric protein complex known as eIF4F, which is the core of cap-dependent translation initiation, binds this 5' cap. However, a second independent initiation mechanism exists that utilizes unique internal ribosome entry sites (IRES) elements to stimulate initiation (see [Internal Ribosome Entry Site-Mediated Translation](#)). IRES elements are highly structured RNA sequences that were originally discovered in viral RNA genomes and have since been identified in a subset of mammalian mRNAs. IRES elements are defined exclusively by functional criteria rather than primary sequence, making their identification difficult. Unlike cap-dependent translation, the mechanisms of IRES-induced ribosome recruitment are only beginning to be understood. Differential

requirement of eIFs by distinct ORES elements provides support for the likelihood of mechanistic variability. In normal cells, global translation is thought to be cap-dependent while certain circumstances can lead to an increase in IRES-dependent translation. This variability has led many to hypothesize that selective translation plays an important role in how cells respond to external cues or stresses (see [Targeted mRNA Degradation](#)).

Cell Death Regulation

Programmed cell death is an organismal and cellular necessity, effectively removing damaged or unwanted cells in a process that minimizes damage to other nearby cells. Apoptosis involves both an extrinsic and intrinsic pathway that sets in motion programmed cell death (see [Apoptosis](#)). Notably, cross talk between the two pathways is possible since both share some common elements. Each cascading pathway contains both pro-apoptotic and anti-apoptotic components whose opposing activities ultimately decide the cell's fate. Specifically, caspases are thought of as the executioners of apoptosis. They consist of a family of cysteine proteases that deliver and execute apoptotic stimuli through their limited proteolysis activity (see [Caspases](#)). Conversely, the BCL family of proteins consists of three subfamilies associated with controlling mitochondrial apoptosis (see [The Bcl-2 Family Proteins: Insights into Their Mechanism of Action and Therapeutic Potential](#)). These are readily divided into anti-apoptotic, pro-apoptotic, and BH3-only proteins. This complicated family division results in a multifaceted network of antagonizing outcomes that either protect or promote apoptosis in response to upstream signals. Inhibitor of apoptosis (IAPs) family of proteins adds an additional layer of apoptotic regulation by inhibiting the function of caspases (see [Inhibitor of Apoptosis Proteins, the Sentinels of Cell Death and Signaling](#)). The eight IAP family members, not surprisingly, appear to play a central role in cancer progression.

The cell mitochondria have always played a central role in producing the majority of intracellular ATP and in participating in many anabolic processes that are required for cell survival. However, additional functions have been ascribed to mitochondria based on its role in various signaling pathways that actively provoke cell death (see [Mitochondria in Cell Death Regulation](#)). As stated above, both intrinsic and extrinsic signals are capable of eliciting a mitochondrial apoptotic response. In this manner, the mitochondria serve as a central location for both pro- and anti-apoptotic components.

Extrinsic cell death signals can come in the form of extracellular ligands or other receptor-mediated interactions. This implies that neighboring cells have the capacity to influence the programmed cell death of other cells either during development or to prevent local tumorigenic invasion. In the latter case, the elimination of tumor cells through induced apoptosis by neighboring cells or through changes in its own micro-environment interactions could serve as a potent antitumor mechanism. One such mechanism is termed anoikis and results when a normal epithelial cell detaches from the extracellular matrix or attaches to an inappropriate type of matrix

(see [Anoikis](#)). The Anoikis response provides protection from tumor cells that might detach from their local environment in order to become metastatic. TNF is a far more complicated ligand that is capable of eliciting both proliferative and apoptosis pathways upon binding to the TNF receptor (see [Tumor Necrosis Factor Signaling Pathways](#)). However, its ability to activate caspases under certain conditions makes it a potent inducer of cell death, particular during viral infection.

When cells are poised to die, their decaying contents must be dealt with by surrounding cells. Recent evidence has pointed toward an equally effective form of cellular recycling termed autophagy. In this setting, intracellular components are degraded in lysosomes to be recycled. This turnover allows for proteins and organelles to be renewed and also serves as a mechanism for quality control of newly synthesized cellular structures (see [Autophagy](#)). Additionally, organ homeostasis is often maintained by the rapid removal of newly apoptotic cells through efferocytosis. In order to prevent the dispersal of internal self-antigens to the extracellular environment, dying cells must be removed in an efficient manner and to promote healing of the surrounding tissue. Efferocytosis is the organism's natural response to both remove dying cells and to promote wound healing (see [Efferocytosis in the Tumor Microenvironment](#)). Not surprisingly, the local environment of the dying cell plays a central role in stimulating its engulfment and clearance.

Cell Cycle Progression

The ability of a cell to achieve an appropriate balance between cell division and arrest requires the coordinated function of primarily two classes of proteins: proto-oncogenes and tumor suppressors. The heightened state of dependence of malignant cells on oncogenes and on the inactivation of tumor suppressor genes underscores the importance of both classes in cancer development. Thus, an understanding of the functional interplay between proto-oncogenes and tumor suppressors under normal conditions as well as how perturbations that offset this balance trigger tumorigenesis is the focus of the first article on this topic (see [Interplay between Oncogenes and Tumor Suppressor Genes in Human Disease](#)).

Both proto-oncogenes and tumor suppressor proteins largely function to drive and stop the cell cycle, respectively. The mammalian cell cycle can be temporally partitioned into four segments: G1, S, G2, and M phases. Alternatively a fifth G0 phase is often termed to describe a quiescent, non-proliferative state into which the cell withdraws upon cessation of growth factor signaling or in response to growth inhibitory cues. During the initial G1 gap phase, the cell is primed by mitogenic stimuli in preparation for the synthesis of an exact replicate of its genetic material during S phase that will be distributed to its resultant daughter cell upon mitotic division in M phase. The second G2 gap phase serves a similar preparatory function as G1, checking the fidelity of replicated DNA and positioning the cell for its proper transition into M phase. Early in G1, external mitogenic stimuli activate several kinase cascades that promote the synthesis and stability of D-type cyclins which partner with cyclin-dependent kinases (CDKs) to drive the cell's progression through G1 (see [Cyclins](#)

and Cyclin-Dependent Kinases). As cells progress through the cell cycle other combinations of cyclins and CDKs (cyclin E-CDK2, cyclin A-CDK2, cyclin B-CDK1) act to further drive events associated with each cell cycle phase. Arguably, one of the most crucial events in the cell cycle is the hyperphosphorylation and inactivation of the retinoblastoma protein (Rb) at the restriction point (see [The Restriction Point](#)). Hyperphosphorylation of Rb derepresses E2F target genes whose transcription is required for the efficient transition from G1 into S phase and subsequent DNA synthesis during S phase (see [S Phase](#)). By maintaining the hyperphosphorylated state of Rb throughout M phase, cyclin-CDK complexes ensure the cell's committed passage through the restriction point to the completion of mitosis.

Two classes of CDK inhibitors (CKIs), the INK4 (p15, p16, p18, and p19) and the CIP/KIP (p21, p27, and p57) families provide an additional layer of regulation to the cell cycle (see [CDK Inhibitors in Normal and Malignant Cells](#)). CKIs are activated in response to either DNA damage or hyperproliferative signals and inhibit the CDK4/6 (INK4 family) or CDK2 (CIP/KIP family) holoenzymes. Whereas the INK4 family members block kinase activity by impairing the binding of CDK4/6 to D-type cyclins, the CIP/KIP proteins form heterotrimeric complexes with partnered cyclins and CDKs to impair their kinase activity. As all of the CKI genes display tumor suppressive functions *in vitro* and *in vivo*, clearly the cell's commitment to replicate and divide is a pivotal decision that is targeted for deregulation in the process of tumorigenesis.

A functionally independent tumor suppressor was identified in 1995 residing between the *INK4A* and *INK4B* tumor suppressor genes on human chromosome 9p21. This gene shares a common second and third exon with *INK4A* but is encoded by a distinct exon 1. The resulting mRNA splices in an alternative reading frame yielding an ARF tumor suppressor protein. Since *INK4A* and ARF are translated in alternative reading frames, they share no resemblance in their protein structure or their cellular function. The ARF tumor suppressor protein largely resides in the nucleolus and binds to the MDM2 proto-oncogene product to indirectly activate the p53 tumor suppressor (see [The INK4a/ARF Locus](#)). Over the last decade, ARF has been shown to also maintain cellular homeostasis through its ability to interact with numerous other proteins independent of p53, many of which have known roles in ribosome biogenesis. This provides a more than coincidental link between cell proliferation and cell growth pathways, squarely placing ARF at the nexus of the two processes. Likewise, p53 has long been labeled the guardian of the genome because of its role in preserving the stability of the genome. The p53 tumor suppressor is a key sensory molecule that regulates a plethora of downstream targets capable of triggering cell cycle arrest, apoptosis, senescence, DNA repair, and autophagy among many others in response to robust cellular stress signals (see [Regulation of the p53 Pathway](#)). While we have learned much about these tumor suppressors in the past decade, their additive list of cellular functions appears nearly limitless.

As proliferating cells travel into mitosis they must ensure the proper segregation of chromosomes prior to completion of the cell cycle. One of the main components of this checkpoint involves the function of the chromosomal passenger complex

(CPC) whose main role is to ensure proper chromosome inheritance in daughter cells (see [Traveling through Mitosis with the Chromosomal Passenger Complex](#)). As cells enter mitosis, this complex associates with centromeres where it monitors the attachment of newly formed spindles to kinetochores, fully capable of destabilizing and removing those attachments that could cause chromosome mis-segregation. Additionally the CPC must properly oversee chromosome positioning to ensure that no chromosomes are trapped in the cleavage furrow and in doing so, the CPC ultimately acts as a guardian of chromosome segregation. Any failure to properly regulate the six stages of mitosis, prophase, prometaphase, metaphase, anaphase, telophase, and cytokinesis could affect the tumorigenic potential of the cell (see [Mitosis in Animal Cells](#)). Moreover, the final step of mitosis is termed cytokinesis in which the cytoplasm of the mother cell is properly partitioned into two daughter cells. Cytoskeletal, membrane trafficking, and cell cycle pathways tightly coordinate the steps leading to the final cleavage furrow to ensure proper cleavage (see [Regulating Cytokinesis](#)). A failure to properly regulate cytokinesis leads to a genetically unstable cell ploidy that can lead to tumorigenesis. Not surprisingly, cancer cells often harbor an altered mitotic program and this has led to an increased focus on identifying mitotic components that could be used to treat cancer. The normal cell is programmed to undergo mitotic catastrophe in order to eliminate cells that have been irreversibly damaged (see [Mitotic Catastrophe](#)). While numerous chromosomal conditions can trigger mitotic catastrophe, cells that evade this process contribute to genome instability and tumor progression. However, using this strategy, many anticancer agents invoke mitotic catastrophe by damaging DNA beyond repair, demonstrating the utility of inducing this mitotic event to treat cancer.

We have seen cells that enter the cell cycle often encounter and interpret a multitude of signals in order to either properly transit the cell cycle or be removed from it. Cellular senescence is a state of permanent cell cycle arrest that was initially observed in cells grown in cell culture (see [Cellular Senescence](#)). Future experiments rapidly redefined the state, arguing that cellular senescence could be seen in tissues, particularly those in the aged. These observations led many to relate cell senescence with the process of aging and while that is certainly true, current viewpoints have placed an emphasis on the role of senescence in response to oncogenic stimulation. In this manner, cellular senescence is seen as a direct response to oncogenic insult, an opposing response to oncogenic transformation.

Functional Cell Biology of Immunity

The battle for homeostasis in the face of pathogens generates intense evolutionary pressure on immune defenses, pushing the boundaries of cell biology. The defensive strategies have been characterized as innate for recognition of evolutionarily conserved signatures of injury and infection, and adaptive when unique receptor repertoires are developed to deal with genetic adaptation of pathogens. A first level of innate immunity is the tissue barriers composed of epithelial coverings (see [Function of Epithelial Barriers](#)) and mesenchymal

connective tissue (see [Roles of Stromal Cells in the Immune System](#)) that together protect the integrity of the organism and provide pathways through tissues for defensive cells. Another type of innate immunity is based on chemical defences, such as the NADPH oxidase of neutrophils and phagocytes that specialize in generation of toxic reactive oxygen species in a tightly controlled manner (see [The Phagocyte NADPH Oxidase: Structure and Assembly of the Key Multicomponent Enzyme of Innate Immunity](#)). Both innate and adaptive immune receptors link to signal transduction and transcriptional pathways that support selection of effector functions and determine proliferation and survival of adaptive clones. These include the nuclear factor- κ B (NF κ B) and nuclear factor of activated T cells (NFAT) transcription factor families (see [NF- \$\kappa\$ B and the Immune System](#) and see [Nuclear Factor of Activated T Cells and Tolerance](#)). Phagocytes include neutrophils (see [Neutrophil Biology](#)), macrophages (see [Specialized Subsets of Tissue-Resident Macrophages in Secondary Lymphoid Organs](#)), and dendritic cells (see [Dendritic Cells](#) and see [Functional Specialization of Dendritic Cell Subsets](#)), which have the capacity to engulf and digest relatively large particles on the order of 1–10 μ m and even larger, which can involve phagocytic synapses (see [Phagocytic Synapses](#)). Phagocytes express many type of ‘scavenger’ receptors that allow them to participate in clearance of aged host proteins and cells or microbe-derived materials (see [Scavenger Receptors](#)). Adaptive immune cells generate unique antigen receptors during their development from progenitors in primary lymphoid tissues: the bone marrow (B cells make B cell receptors, BCR) and thymus (T cells make T cell receptors, TCR) (see [V\(D\)J Recombination: Orchestrating Diversity without Damage](#)). Once the BCR and TCR are made these cells undergo selection processes to eliminate auto-reactive cells (negative selection) and in the case of T cells a process of positive selection that ensures that T cells are predisposed to recognize appropriately processed antigens. Antigen processing is discussed in the context of dendritic cells, which are the primary antigen-presenting cells for initiation of immune responses (see [Dendritic Cells](#) and see [Functional Specialization of Dendritic Cell Subsets](#)). Antigen presentation requires the partial proteolysis of proteins to generate peptides that bind the major histocompatibility complex (MHC) proteins, which are expressed on the surface of the antigen-presenting cell. The TCR and peptide–MHC will span about 15 nm when engaged in the interface between T cells and antigen-presenting cells and this close proximity is facilitated by adhesion molecules in close coordination with the actin cytoskeleton (see [Cellular Structures Controlling T Cell Signaling in Time and Space](#)). The TCR interaction with the peptide–MHC complex is weak in solution, but is perfectly adapted to operate in a synaptic junction. The basic chemistry and physics of this environment is an area of active study (see [Single Molecule Methods to Measure Receptor–Ligand Interaction in Immunological Synapses](#); see [T Cell Receptor Triggering](#)). The downstream signal transduction process is well defined, although there are many nuances to this including how distinct co-stimulatory signals are integrated with TCR signals (see [The T-Cell Receptor Signalingosome](#)). We would define the immunological synapse as a (1) stationary cell–cell junction, (2) built from bona fide adhesion molecules, (3) with contiguous membranes, and (4)

vectoral communication by secretion (see [Introduction to Functional Cell Biology of Immunity](#)). One of the most important functions of the immunological synapse is in cytotoxicity mediated by CD8 T cells (see [T Cell Memory to Viral Infections](#)). Another setting for immunological synapse function is T cell help which is based on recognition of peptides presented by MHC class II and is critical for generation of high affinity antibodies (see [T Follicular Helper Cells](#)). A second major class of T cells that recognize peptides presented by MHC class II are referred to as regulatory T cells and they have adapted the immunological synapse to regulate the function of antigen-presenting cells through *trans*-endocytosis (see [CD28 Costimulation and Regulatory T Cells](#)). Cell populations within the bone marrow are maintained by chemokines (see [CXCL12/SDF-1 and Hematopoiesis](#)). Secondary lymphoid tissues serve as an important barrier to systemic pathogen spread and a hub for adaptive immunity (see [Roles of Stromal Cells in the Immune System](#)). Specialized endothelial cells control access to secondary lymphoid tissues and serve as inducible entry points into inflamed tissues (see [Lymphocyte–Endothelial Interactions](#)). These articles highlight the unique cell biology of the immune system and point to open questions accessible to tools of the cell biologist.

Stem Cell Biology

Stem cell biology has become a very active field in the last decade, due not only to the fascinating fundamental biology that has been uncovered, but also due to the application of discoveries in the field to therapeutic design for regenerative medicine. In these articles, a temporal snapshot of the field is presented that seeks to provide both experts and the students alike with a range of current lines of investigation into stem cell biology. These articles focus primarily upon adult stem cells, also referred to as progenitors that are responsible for maintaining tissue homeostasis and driving regeneration as opposed to embryonic stem cells (ES cells), which are formed during early embryogenesis and give rise to all tissues of the body. First we consider the adult stem cell in its cellular context in a number of tissues (see [The Adult Stem Cell Niche: Multiple Cellular Players in Tissue Homeostasis and Regeneration](#)). We examine tissues that are capable of robust regeneration such as the skin or skeletal muscle and the central role stem cells play in this process as well as their reliance on locally delivered cues from neighboring cells or their niche. We also examine tissues that are relatively incapable of regeneration such as the heart or brain and examine why this may be the case and how the niche may be different. We then turn our attention to the unique metabolic signature of stem cells (see [Metabolic and Energetic Regulation of Stem Cells](#)). Here we explore how the metabolic state of stem cells is different than other somatic cell types in the body and how this unique metabolic state may underlay their stem cell capacity and ability to respond to cues from the environment to expand and differentiate. Linked tightly with both the stem cell niche and the metabolic state of these stem cells is the age of the organism in which they are found. In the following article (see [Stem Cells and Aging](#)), we examine the molecular changes that occur in the ageing stem cell. Even in quiescent stem cells such

as muscle satellite cells, changes occur that render them less responsive to their environment and less capable of maintaining tissue integrity or properly executing a complete regenerative response. It has been found that stem cells lose their capacity to expand (proliferate) or that they fail to replenish a pool of stem cells (self-renew) as a reserve that is essential to the long-term health of the tissue. While the 'normal' course of ageing leads to a decrease in stem cell mitotic capacity, it has also been proposed that when stem cells lose the ability to either remain in quiescence or to differentiate, they enter of phase of unchecked proliferation leading to cancer. In the following article, (see [Cancer Stem Cells](#)), we examine the cancer stem cell hypothesis and examine a specific setting in which stem cells can be clearly demonstrated to be the cancer source and that once formed, the cancer maintains a 'stem-like' cell that gives rise to partially differentiated tumor cells. It is perhaps the focus of this article that also outlines an optimal cellular target for cancer treatment but also the potential risks in therapies aimed at increasing the proliferative potential of stem cells in chronic disease or ageing. A survey of stem cells would be incomplete if it did not take into account one of the most important paradigm shifts in the field which is the discovery of a means to derive pluripotent stem cells from ordinary somatic cells such as fibroblasts (see [Pluripotent Cells: New Tools for Disease Research and Therapies](#)). These cells, referred to as iPS cells (induced pluripotent stem cells) behave

quite similarly to ES cells and can be triggered to differentiate into most all of the tissues found in the body. From a fundamental viewpoint, this is remarkable as it involves erasing much of the epigenetic signature in the adult-derived fibroblast and reprogramming the cell completely. These cells have several potential clinical uses including the use as donor cells for engraftment into damaged tissue as well as for therapy screens to design drugs or the best combination of drugs for a specific patient suffering from a tissue-specific disease. Drugs that correct heart arrhythmias in one patient do not always work for another who presents seemingly identical symptoms. The patient's cells can be used to prescreen for a tailored or 'personalized medicine' approach. Lastly, we examine how the epigenome, which refers to modifications made to the DNA of the genome without changing the DNA itself is an important player in governing stem cell competence and identity (see [Epigenetic Regulation of Stem Cells](#)). This can be brought about by DNA methylation or modification of the histones via acetylation. Drugs that target the enzymes that drive histone acetylation are already in use for cancer treatment, and it is suggested that this same family of drugs may have a major potential potentiating regeneration of diseased tissue. While this collection of topics is not meant to be exhaustive, it covers many of the key topics of investigation in adult stem cell research today that will be the basis of future stem cell research and responsible for new cures in regenerative medicine.

Glossary

Adaptor molecules Molecules without intrinsic enzymatic activity which serve to connect other signaling molecules with each other.

Autophosphorylation A kinase phosphorylates itself or a companion molecule in a dimer.

Endocytosis Internalization of membrane-bound molecules into intracellular vesicles (endosomes).

Growth factor A ligand, normally a protein, which binds to a receptor at the cell membrane and promotes cell proliferation.

Shedding Proteolytic cleavage of membrane proteins releasing their extracellular domains.

Introduction

Cells within a multicellular organism communicate with each other, by direct cell–cell or cell–matrix interactions or by release of molecules that bind to and activate receptors on the surface of, or inside, the receiving cell. Several growth factors and cytokines bind to plasma membrane-bound receptors associated with kinase activities. Certain receptors have intrinsic kinases, as are the cases for members of the large family of receptor tyrosine kinases (RTKs) and for members of the smaller family of receptor serine/threonine kinases. Other receptors, particularly those binding cytokines that have important functions to regulate immune cells, lack intrinsic kinase activity, but associate with intracellular tyrosine kinases that are activated upon ligand binding (Heldin *et al.*, 2014).

This review will focus on RTKs. First, we will describe some general features of RTK relating to their activation, turnover,

and signaling mechanisms, then we will comment on the structural and functional properties of each RTK family, and finally we will discuss their involvement in disease.

Families of RTKs and Their Ligands

RTKs have important functions in the regulation of the embryonal development, and in the regulation of wound healing and tissue homeostasis in the adult. RTKs have an extracellular, ligand-binding part, which is composed of different combinations of domains, for example, immunoglobulin (Ig)-like, fibronectin type III, cysteine-rich, epidermal growth factor (EGF)-like, cadherin-like, and discoidin-like domains (Blume-Jensen and Hunter, 2001; Lemmon and Schlessinger, 2010). A single transmembrane segment connects the extracellular part with the intracellular part, which harbors the kinase domain together

Figure 1 RTK families. The 20 RTK subfamilies and their characteristic structural domains are shown. Reproduced with permission from Lemmon, M.A., Schlessinger, J., 2010. Cell signaling by receptor tyrosine kinases. *Cell* 141 (7), 1117–1134.

with juxtamembrane and C-terminal sequences. Certain RTKs, in addition, have a characteristic insert in their kinase domain which protrudes from the kinase domain after it has been folded (Locascio and Donoghue, 2013; Figure 1).

Based on their structural properties, the 58 RTKs encoded in the human genome can be divided into 20 subfamilies (Blume-Jensen and Hunter, 2001; Lemmon and Schlessinger, 2010; Figure 1). A prototypic example is the EGF receptor family which consists of the EGF receptor, ErbB2, ErbB3, and ErbB4. Each RTK family corresponds to a family of structurally related ligands; the EGF family consists of 11 members (Citri and Yarden, 2006). Normally, each receptor binds more than one of the ligands in the family, and each ligand binds more than one receptor in the family (Table 1). Binding of ligands

outside the family has been observed, but is rare; examples include the Ryk and Ror RTKs which bind certain members of the Wnt family that have Frizzled receptors as their canonical receptors (van Amerongen *et al.*, 2008).

Some ligands are secreted as soluble molecules which may or may not need to undergo proteolytic activation. Other ligands are synthesized as transmembrane proteins; in some cases the transmembrane molecule is cleaved to release the ligand, in other cases the ligand presented on one cell may activate a receptor in another cell. In the case of ephrins and RTKs of the Eph receptor family, there are also examples of retrograde signaling, where the Eph 'receptor' by interacting with the ephrine 'ligand' induces signaling events in the ligand-bearing cell (Pasquale, 2008).

	AATYK3	Unknown	

^aLigand-receptor interactions of lower affinities are indicated by brackets.^bIncludes all FGFR splice forms and data represent *in vitro* activity which varies considerable between different FGF-FGFR combinations.^cInteracts with Lrp4 on the target cell and this is required for MuSK receptor dimerization and activation.

RTKs Undergo Ligand-Induced Dimerization

Many, maybe all, RTKs are activated by ligand-induced dimerization (Heldin, 1995; Lemmon and Schlessinger, 2010). The juxtaposition of the intracellular parts of the receptors makes it possible for one receptor molecule to phosphorylate the other *in trans*, a process that is referred to as autophosphorylation.

Dimerization of RTKs can occur by different mechanisms. Certain ligands are dimeric molecules that bind their receptors in a symmetric manner; in the case of nerve growth factor (NGF), the ligand acts as a bridge between the receptors and the receptors do not touch each other (Wehrman *et al.*, 2007), whereas in the cases of platelet-derived growth factor (PDGF) (Yang *et al.*, 2008), colony stimulating factor 1 (CSF1) (Chen *et al.*, 2008) and stem cell factor (SCF) (Yuzawa *et al.*, 2007) receptors the dimeric configuration is stabilized by interactions both between the ligands and the receptors, and by direct receptor–receptor interactions. Direct interactions between Eph receptors also appear to be important for their oligomerization and activation (Seiradake *et al.*, 2010).

The situation is very different for the EGF receptor family. These receptors have four extracellular domains; the monomeric ligand binds to domains I and III, which causes a dramatic change in conformation unmasking a dimerization arm in domain II which promotes direct receptor–receptor interaction, but the ligand itself does not take part in bridging between the two receptors (Burgess *et al.*, 2003). Moreover, the dimerization of receptors in the EGF family is dependent on an interaction between the N-terminal parts of the transmembrane helices, which promotes an antiparallel interaction between the juxtamembrane sequences releasing the inhibition by the membrane (Arkhipov *et al.*, 2013; Endres *et al.*, 2013).

Yet another variation on the dimerization theme is exemplified by fibroblast growth factor (FGF) receptors; in this case the binding of the monomeric ligand is stabilized by heparin/heparan sulfate polysaccharide chains (Schlessinger *et al.*, 2000). A 2:2:2 complex is formed in which each FGF molecule contacts both receptor molecules in the dimer, heparin/heparan sulfate contacts both ligand and receptor, and the two receptors contact each other.

There are indications that certain RTKs form dimers already before ligand binding, and members of the insulin receptor family are even disulfide-bonded dimers. In these cases, ligand binding is likely to induce a conformational change that activates the receptor kinases. There are indications that the relative orientation of the receptors in the dimer is important for the activation (Jiang and Hunter, 1999). Moreover, an initial ligand-induced dimerization may be followed by oligomerization into large clusters, which may be important for activation of, for example, the Tie2 (Barton *et al.*, 2006) and Eph (Himanen and Nikolov, 2003) RTKs.

Dimerization Activates the Kinase Activity of RTKs

The autophosphorylation that follows ligand-induced RTK dimerization has two important consequences, i.e., it changes the conformation of the receptor promoting activation of its

kinase, and it provides docking sites for SH2 domain containing signal transduction molecules.

The kinases of RTKs are kept inactive by one or more mechanisms involving the activation loop of the kinase domain, the juxtamembrane segment, or the C-terminal tail of the receptor. Autophosphorylations in these regions are connected with release of the kinase activity. Thus, in the resting state, the activation loop of most RTKs is folded over the active site of the kinase, thereby preventing ATP to access its pocket; the phosphorylation of a conserved tyrosine residue in the activation loop causes a conformational change moving it away from the active site. This mechanism for control of the kinase action appears to prevail for most RTKs, exceptions include members of the EGF receptor family (Zhang *et al.*, 2006) and Ret (Knowles *et al.*, 2006). The juxtamembrane segment is in the resting state of certain RTKs, including MuSK (Till *et al.*, 2002), Flt3 (Griffith *et al.*, 2004), the SCF receptor (Mol *et al.*, 2004) and Eph family members (Wybenga-Groot *et al.*, 2001), also folded over the active site; phosphorylation in this segment changes its conformation and moves it away from the active site (Hubbard, 2004). Finally, the C-terminal tail of some RTKs, including Tie2 (Shewchuk *et al.*, 2000), Ron (Yokoyama *et al.*, 2005) and probably also the PDGF β -receptor (Chiara *et al.*, 2004), can be folded over the kinase domain to inhibit the kinase activity; phosphorylation of certain tyrosine residues in the tail makes it swing open and allows activation of the kinase.

It is not obvious how the juxtaposition of two inactive kinase domains can lead to autophosphorylation *in trans* between the receptors. It is possible that the kinases are not completely inactive in the resting state and their juxtaposition may start the activation process in a reciprocal manner. Moreover, in the case of the EGF receptor family, a phosphorylation-independent mechanism for activation of the receptor kinase in the dimer has been elucidated. Thus, the C-terminal lobe of one kinase domain makes contact with the N-terminal lobe of the other, thereby activating it (Zhang *et al.*, 2006). Interestingly, the juxtamembrane segment, which in other RTKs has an inhibitory role, is needed to stabilize the interaction (Jura *et al.*, 2009, 2011; Red Brewer *et al.*, 2009).

Ligand binding induces homodimerization of RTKs, however, heterodimeric complexes can also be formed, for example, in the case of the EGF (Citri and Yarden, 2006), PDGF (Heldin and Lennartsson, 2013) or vascular endothelial growth factor (VEGF) (Olsson *et al.*, 2006) receptor families. Since downstream signaling depends on autophosphorylation of specific tyrosine residues in the RTKs, differences in the autophosphorylation patterns between homo- and heterodimeric receptors, will result in different signaling properties.

Signaling Downstream of RTKs

In addition to activating the kinases of RTKs, ligand-induced autophosphorylation of the receptors provide docking sites for SH2 domain-containing signaling molecules. The SH2 domains recognize phosphorylated tyrosine residues in a certain environment; in particular, the 3–6 amino acid residues on C-terminal of the phosphorylated tyrosine determine the specificity of SH2 domain binding (Songyang and

Figure 2 Schematic representation of signaling induced by receptor tyrosine kinases. Phosphorylated tyrosine residues in the ligand-activated receptor serve as docking sites for signaling proteins containing SH2 or PTB domains, which subsequently activates intracellular signaling pathways, for example Src, PI3K, MAPK, PLC γ , and SHP2. Another signaling mechanism includes proteolytic release of the intracellular tyrosine kinase domain, which is initiated by a protease cleaving the receptor extracellularly (1) followed by a subsequent proteolysis in the transmembrane segment (2). The released intracellular receptor fragment translocates into the nucleus where it can influence gene expression. In addition, the entire receptor can be translocated to the nucleus or, in certain cases, to the mitochondria.

Cantley, 2004). Autophosphorylation sites binding SH2 domains are often located in the juxtamembrane, kinase insert and C-terminal tail regions of the receptors, but more rarely in the kinase domains.

In addition to autophosphorylation sites in the receptors themselves, additional phosphorylation sites are found on scaffolding proteins that bind to the receptors in a selective manner. Thus, RTKs of the insulin receptor family bind the 4 members of the insulin receptor substrate (IRS) family, FGF and NGF receptors bind FRS2 α and β , and several RTKs bind Gab1 or Gab2. Formation of such multi-protein tyrosine-kinase-dependent complexes is important in RTK signaling (Pawson, 2004).

Of the SH2 domain-containing molecules that bind to phosphorylated tyrosines in RTK complexes, certain have intrinsic enzymatic activities, such as members of the Src family of tyrosine kinases, members of the SHP family of tyrosine phosphatases, GTPase-activating protein (GAP) for Ras, phospholipase C γ (PLC γ), and members of the Cbl family of ubiquitin ligases (Figure 2). Other receptor-interacting SH2 domain-containing molecules form stable complexes with enzymes, for example, Grb2 which forms a complex with SOS1, a guanine nucleotide exchange factor (GEF) for Ras, and the phosphatidylinositol-3'-kinase (PI3-kinase) regulatory subunit p85 which forms a complex with the catalytic subunit p110. Some RTKs also activate members of the signal transducer and activator of transcription (STAT) family, which after phosphorylation and activation are translocated to the nucleus where they regulate transcription by binding to the promoters of certain genes. Finally, RTKs bind certain adaptor molecules, such as Shc, Crk, and Nck, that contain, in addition to SH2 domains, other domains mediating interactions with certain proteins or phospholipids of membranes. Examples of such

domains are SH3- and WW-domains that recognize Pro-rich regions, PTB-domains that bind tyrosine-phosphorylated regions although the dependence on phosphorylation is not absolute, PDZ-domains that recognize a C-terminal Val residue or certain other bulky hydrophobic residues, and PH-, PX-, C1-, C2-, and FYVE-domains that recognize phospholipids. The common occurrence of the latter domains in signaling molecules reflects the fact that much signal transduction activities occur at the inner leaflet of the plasma membrane or close to membranes of intracellular vesicles.

Certain of the members of the RTK family have no, or low, kinase activity, for example, ErbB3, CCK4, EphB6, and Ryk, since they lack critical catalytic amino acid residues. Still, these receptors have important roles in signal transduction by acting as phosphorylatable scaffold molecules in heterodimers with other kinase-active RTKs.

Given that there is a limited number of signaling pathways activated downstream of RTKs, an interesting question is how specificity can be achieved. The binding specificities of SH2 domains provide a basis for specificity in signal transduction, where a given RTK may activate certain signaling pathways, but not others. However, the formation of large scaffolds with many phosphorylated tyrosines means that activation of most of the RTKs leads to activation of most of the signaling pathways induced by the binding of SH2 domain-containing molecules. Adding to the complexity is also the fact that there is an extensive cross-talk between the signaling pathways, creating an intracellular signaling network rather than linear signaling pathways (Lemmon and Schlessinger, 2010).

Another mechanism of signaling via certain RTKs, involves ligand-induced cleavage of the receptor just outside the cell membrane by metalloproteases, for example, ADAM17, followed by another cleavage in the transmembrane region by

γ -secretase, whereby the cytoplasmic part of the receptor is translocated to the nucleus where it may regulate transcription. Such a mechanism was originally described for ErbB4 (Ni *et al.*, 2001), but has subsequently been observed also for several other RTKs, including the CSF-1 receptor, EphB2, PTK7, Ret, Met, Ron, Ryk, Tie1, FGF receptor 3, and VEGF receptor 1 and 2 (Carpenter and Liao, 2013), as well as the receptors for insulin (Kasuga *et al.*, 2007) and IGF-I (McElroy *et al.*, 2007). In the case of ErbB4 the intracellular part forms a complex with TAB2 and the corepressor N-CoR which represses the transcription of several glial genes and thereby inhibits the formation of astrocytes (Sardi *et al.*, 2006). In addition, the ErbB4 intracellular domain has been found to associate with mitochondria and promote apoptosis of breast cancer cells (Naresh *et al.* 2006).

A consequence of the shedding of the extracellular domains of RTKs by ADAM17, or by other proteases, is that the released extracellular domain may scaffold the corresponding ligand and thus cause decreased signaling (López-Otín and Hunter, 2010).

In addition, certain RTKs, including members of the EGF receptor family, the IGF-I receptor, Ron, Met, FGF receptor 1 and 2, and VEGF receptor 1 and 2 can be translocated in uncleaved forms to the nucleus (Carpenter and Liao, 2013; Massie and Mills, 2006; Song *et al.*, 2013). It appears that the RTKs are mainly present in the nucleoplasm rather than in the nuclear envelope. Trafficking of the EGF receptor from the cell surface to the Golgi occurs in a microtubule-dependent manner and fusion with the Golgi involves syntaxin 6-mediated membrane fusion (Du *et al.*, 2014). ErbB2 (Wang *et al.*, 2004) and the EGF receptor (Lin *et al.*, 2001; Lo *et al.*, 2005) have been shown to regulate transcription in cooperation with other nuclear factors. The physiological implication of the translocation full-length RTKs into the nucleus, however, remains to be elucidated.

In addition, the intact ErbB2 molecule has been found to be translocated to the mitochondria, via association with mtHSP70, where it negatively regulates respiratory functions in a kinase-dependent manner (Ding *et al.*, 2012).

RTK Coreceptors

Signaling via RTKs is modulated by interactions between RTKs and other molecules expressed on the plasma membrane. Thus, certain RTKs interact with receptors for extracellular matrix molecules, such as CD44 that binds hyaluronan (Orian-Rousseau, 2010), and integrins that bind collagen, fibronectin, or laminins (Ivaska and Heino, 2011). Low-density lipoprotein (LDL) receptor-related proteins (LRPs) also interact with certain RTKs. Thus, the heparin sulfate proteoglycan agrin binds LRP4 and thereby activate the RTK MuSK (Kim *et al.*, 2008). On the other hand, LRP interacts with PDGF receptors and suppresses their signaling (Boucher *et al.*, 2002; Loukinova *et al.*, 2002). Other examples of RTK coreceptors are glial-derived neurotrophic factor (GDNF) receptor α , a glycosylphosphatidylinositol (GPI)-anchored molecule that is needed for GDNF to bind to and activate the RTK Ret (Schlee *et al.*, 2006), and neuropilin 1 and 2 that cooperate with VEGF receptors (Olsson *et al.*, 2006).

Feedback and Amplification of RTK Signaling

In the early phase after stimulation of RTK signaling, amplification mechanisms assure that a high level of signaling is rapidly achieved. For example, reactive oxygen species (ROS) are produced in a PI3 kinase-dependent manner (Bae *et al.*, 1997), which inhibit PTPs by oxidizing a cysteine residue in their active site (Tonks, 2006) and thereby enhance tyrosine phosphorylation. Another example is activation of the ADAM family of proteases downstream of EGF receptors, which cleaves and activates membrane-bound heparin-binding (HB) EGF further activating the EGF receptors through autocrine stimulation (Hynes and Schlang, 2006).

At later stages various feedback mechanisms are engaged to control RTK signaling. Examples include the docking of PTPs of the SHP family to the receptors, which leads to dephosphorylation of RTKs, as well as the docking of RasGAP which counteracts the activation of Ras. In addition, protein kinase C (PKC), which is activated downstream of PLC γ , is involved in feedback control by phosphorylating and inactivating certain RTKs, such as the EGF receptor (Hunter *et al.*, 1984), the insulin receptor (Bollag *et al.*, 1986), Met (Gandino *et al.*, 1990) and the SCF receptor (Blume-Jensen *et al.*, 1993).

Activation of RTKs rapidly leads to the induction of immediate-early genes, which encode different effector molecules involved in stimulation of cell proliferation, survival, and migration. Thereafter, delayed-early genes are induced, several of which encode proteins that suppress signaling. Examples of inhibitory mechanisms downstream of several RTKs include FOSL1, which binds to and inhibits AP1 transcription factors activated by RTKs; the transcription factor Id2, which inhibits the TCF transcription complex; dual specificity phosphatases (DUSPs), which dephosphorylate and inactivate MAP kinases; and ZFP36, which recognizes AU-motifs in the 3' end of mRNA molecules and promotes their degradation (Amit *et al.*, 2007). With regard to the EGF receptor, a number of additional feedback mechanisms occur, including induction of NAB2, LRIG-1, Kerkon-1, and Mig6 that inhibit the receptor itself, induction of Argos that sequesters ligand, and induction of Sprouty that has several inhibitory effects on downstream signaling (Citri and Yarden, 2006; Shilo, 2005).

Internalization of RTKs

Ligand binding induces clustering of RTKs in coated pits at the cell surface, whereafter the ligand-receptor complex is internalized via a clathrin-dependent pathway (Zwang and Yarden, 2009), but other internalization routes, for example, caveolin-dependent endocytosis, macropinocytosis, or phagocytosis, also occur (Parachoniak and Park, 2012; Schmees *et al.*, 2012; Sorkin and Goh, 2009). Signaling via RTKs continue after internalization until the pH of the endosomes drops to such a low value that the ligand dissociates from the receptor and the receptor is dephosphorylated by PTPs (von Zastrow and Sorkin, 2007). Interestingly, signaling via RTKs at the plasma membrane differ qualitatively from RTK signaling at endosomes, maybe because of differences in the location of downstream signaling molecules (Miaczynska *et al.*, 2004). In the case of VEGF receptor 2 and 3, the Eph receptor ligand

ephrin-B2 has been found to promote endocytosis, and absence of ephrin-B2 leads to diminished VEGF receptor signaling through Rac1, Akt, and Erk1/2 (Sawamiphak *et al.*, 2010; Wang *et al.*, 2010). Ephrin-B2 has also been found to control the internalization and signaling of the PDGF β -receptor in vascular smooth muscle cells (Nakayama *et al.*, 2013). Moreover, the adaptor protein Dab2, the polarity factor PAR3 and atypical PKC isoforms have been shown to regulate VEGF receptor endocytosis; properly controlled endocytosis has been found to be necessary for angiogenesis in the retina (Nakayama *et al.*, 2013).

Ubiquitination of RTKs by ubiquitin ligases of the Cbl family, and possibly also other E3 ligases, promotes their recognition by components of the endosomal sorting complex required for transport (ESCRT) machinery, which facilitates translocation to multivesicular bodies and degradation in lysosomes (Raiborg and Stenmark, 2009). In the case of the EGF receptor, Cbl initially modifies the receptor by monomers of the ubiquitin-like molecule Nedd8 (Oved *et al.*, 2006). Thereafter, Cbl mono- and poly-ubiquitinates the receptor (Haglund *et al.*, 2003; Huang *et al.*, 2006; Mosesson *et al.*, 2003). The receptor is then recognized by ubiquitin binding proteins of the clathrin coat, such as Eps15, Epsin1-3, and Hrs, to promote the transport to the ESCRT machinery (Avraham and Yarden, 2011). Alternatively, RTKs can be sorted to recycling via fast recycling vesicles characterized by expression of Rab4a, or via slow recycling vesicles characterized by expression of Rab11. After recycling and return to the plasma membrane, the RTK can serve again. Thus, recycling enhances RTK signaling. The balance between sorting to degradation vs. sorting to recycling can be affected by posttranslational modifications of the RTK and can significantly affect the amplitude of signaling (Hellberg *et al.*, 2009; Mosesson *et al.*, 2008; Parachoniak and Park, 2012).

Structural and Functional Properties of RTK Families

The EGF Receptor Family

The EGF receptor family consists of four members, i.e., the EGF receptor, ErbB2, ErbB3, and ErbB4 (Citri and Yarden, 2006). Their extracellular parts consist of four domains; ligand binding occurs to domains I and III, whereby a dramatic relocation of the cysteine-rich domains II and IV occur. Interestingly, ErbB2 does not bind any ligand; its extracellular domain is constitutively in the activated configuration and it takes part in signaling by forming heterodimers with other members in the family. Also notable is the fact that the intracellular kinase of ErbB3 lacks critical amino acid residues involved in catalysis, and therefore has no, or very low, kinase activity; it functions by forming dimers with other members of the family acting as a phosphorylatable scaffold. In particular, ErbB3 mediates a powerful activation of PI3-kinase.

There are 11 ligands in the EGF family; 7 of these bind to the EGF receptor, 2 to ErbB3 and 5 to ErbB4 (Table 1). Several of the receptors thus bind to more than one ligand, and some of the ligands bind to more than one receptor. Certain of the ligands are synthesized as transmembrane proteins, for

example, EGF itself or HB-EGF, that need to be cleaved off before they can bind to receptors.

Deletion of the EGF receptor gene in mice has revealed important roles in the development of epithelial cells in several organs, including skin, lung, intestine and placenta (Miettinen *et al.*, 1995; Sibilio and Wagner, 1995; Threadgill *et al.*, 1995). Knockout mice that survive after birth develop neurodegeneration (Sibilio *et al.*, 1998). Mice in which ErbB2 (Lee *et al.*, 1995) or ErbB4 (Gassmann *et al.*, 1995) has been deleted display defect cardiac development; trabeculae do not develop and the heart beats are irregular. In ErbB3 knockout mice trabeculation is delayed but normal, however, atrioventricular valves are dilated and thinned (Riethmacher *et al.*, 1997).

The Insulin Receptor Family

The insulin receptor family consists of three members, i.e., the insulin receptor and the IGF-I receptor, binding insulin and IGF-I, respectively, and the insulin receptor-related receptor for which no ligand is known (Ward *et al.*, 2007). The insulin receptor occurs as two splice forms, A and B; the A isoforms binds, in addition to insulin, also IGF-II. The members of the insulin receptor family are synthesized as precursor molecules that undergo proteolytic cleavage in the extracellular part, creating α - and β -chains that are held together by disulfide bonds. In addition, two α -chains are bound together with disulfide bonds, giving the receptors a heterotetrameric configuration. The extracellular domains of the insulin receptor consists of two leucine-rich domains separated by a cysteine-rich domain, and three FNIII domains; its three-dimensional configuration resembles a reverted V (Ward *et al.*, 2007).

The insulin receptor regulates lipid, protein, and carbohydrate metabolism, in particular glucose homeostasis (Kitamura *et al.*, 2003), whereas the IGF-I receptor regulates normal growth and development (Adams *et al.*, 2000). Insulin and IGF-I receptors also regulate longevity, as has been shown in different animal models from nematodes to the mouse (Giannakou and Partridge, 2007).

The PDGF Receptor Family

The PDGF receptor family consists of PDGF α - and β -receptors, SCF receptor (Kit), CSF-1 receptor (Fms) and the Flt3 receptor. These receptors are characterized by extracellular parts consisting of five Ig-like domains and an intracellular kinase containing a rather long kinase insert region.

The ligands for the PDGF receptor family of RTKs are all dimeric molecules. The PDGF α - and β -receptors bind homodimers of PDGF-A, -B, -C and -D polypeptide chains and the PDGF-AB heterodimer, the CSF-I receptor binds CSF-1 and interleukin-34, and the SCF receptor and Flt3 bind one ligand each. The ligands of this family bind to Ig domains 2 and 3 of their receptors; after ligand-induced dimerization, Ig-domains 4 and 5 stabilize the dimer by direct receptor-receptor interactions (Verstraete and Savvides, 2012; Yuzawa *et al.*, 2007). Binding of the distantly related VEGF-A to the PDGF α - and β -receptors has been reported (Ball *et al.*, 2007), but the physiological significance of this finding remains to be elucidated.

PDGF receptors have important functions during the embryonal development, as elucidated by knocking out the genes for PDGF isoforms or PDGF receptors in mice (Andrae *et al.*, 2008). Often the PDGF isoforms are produced by epithelial or endothelial cells and act in a paracrine manner on neighboring mesenchymal cells, such as fibroblasts, smooth muscle cells, and pericytes. Knockout of the PDGF α -receptor led to defects in neural crest mesenchymal derivatives, such as the cardiac outflow tract, the thymus, and skeletal components in the facial and other regions, and in the development of the palate and teeth (Soriano, 1997). PDGF α -receptor also mediates signals that are needed for the development and differentiation of oligodendrocyte progenitor cells (Calver *et al.*, 1998) and retinal astrocytes (Fruttiger *et al.*, 2000).

Knockout of the PDGF β -receptor led to abnormal development of the glomeruli in the kidney due to defect development of mesangial cells (Soriano, 1994), capillary microaneurysm (Lindahl *et al.*, 1997), cardiac defects (Van den Akker *et al.*, 2008), and placental defects (Ohlsson *et al.*, 1999).

In the adult, PDGF β -receptor controls the interstitial fluid pressure in tissues and thereby prevents edema (Rodt *et al.*, 1996). The mechanism involves integrin-mediated contacts between fibroblasts and myofibroblasts and extracellular matrix molecules; activation of the PDGF β -receptor causes contraction of the cells and thereby also of the tissue (Lidén *et al.*, 2006). Activation of PDGF receptors on cells involved in wound healing, such as fibroblasts, smooth muscle cells, neutrophils and macrophages, promotes healing of the wound (Robson *et al.*, 1992).

The SCF receptor is expressed in primitive hematopoietic cells and promotes survival and proliferation of these cells in synergy with other cytokines. The SCF receptor is also expressed on melanocytes and has been shown to be important for the migration of these cells from the neuronal crest to the dermis during development (Wehrle-Haller, 2003); defects in SCF receptor signaling was found to lead to pigmentation defects found in patients with piebald disease. SCF receptor knockout mice had reduced fertility (Blume-Jensen *et al.*, 2000; Kissel *et al.*, 2000) and were also constipated because of loss of interstitial cells of Cajal, which functions as pacemaker cells (Huizinga *et al.*, 1995; Ward *et al.*, 1995); they also had defects in spatial learning (Kataguchi *et al.*, 2000; Motro *et al.*, 1996).

The CSF-1 receptor is critical for the proliferation and differentiation of mononuclear phagocytic cells, such as monocytes, tissue macrophages, microglia, osteoclasts, and antigen presenting dendritic cells (Hamilton, 2008). Signaling via Flt3 is important for early haematopoiesis, particularly the proliferation of haematopoietic stem cells and B cell progenitors (Stirewalt and Radich, 2003).

The VEGF Receptor Family

The three members of the VEGF receptor family are characterized by 7 Ig-like domains extracellularly, except that Ig domain 5 in VEGF receptors is replaced by a disulfide bond (Olsson *et al.*, 2006). The kinase domains of VEGF receptors have characteristic insert regions. The VEGF family of ligands is

dimeric molecules and consists of 5 members, i.e., VEGF-A, -B, -C, and -D, and PlGF; they bind to Ig domain 2 and 3.

VEGF receptors have important roles in the establishment and maintenance of the blood and lymphatic vascular systems. Mice with the VEGFR1 gene deleted die at embryonic day 8.5–9.0 by vascular disorganization due to endothelial cell overgrowth (Fong *et al.*, 1995) and increased hemangioblast commitment (Fong *et al.*, 1999), suggesting that VEGFR1 has an inhibitory role in angiogenesis. Knockout of the VEGFR2 gene leads to embryonic lethality day 8.5–9.5 due to defective blood island formation and vasculogenesis (Shalaby *et al.*, 1995).

VEGFR3 has a specific role in the formation of the lymphatic system (Tammela and Alitalo, 2010). However, VEGFR3 knockout mice show embryonic lethality before the formation of the lymphatic system, due to cardiovascular failure (Dumont *et al.*, 1998), suggesting that VEGFR3 also is important for the development of the blood vascular system.

The FGF Receptor Family

The FGF receptor family has 4 members that are characterized by three Ig domains extracellularly; Ig-domain 3 is subject to differential splicing events which alters the ligand-binding specificities of the receptors (Goetz and Mohammadi, 2013). There are 18 ligands in the FGF family; whereas 15 members mainly act locally in a paracrine manner as is common for most RTK ligands, 3 of the FGF family members, FGF-19, -21, and -23, act in an endocrine, hormone-like manner.

FGF receptors are expressed on many cell types and have important roles during the embryonal development, including mesoderm patterning and development of several organ systems, and in the regulation of angiogenesis and wound healing in the adult (Turner and Grose, 2010). Loss of function mutations in the FGFR1 gene lead to Kallmann syndrome 2, which is characterized by hearing loss, cleft palate and tooth agenesis (Dode *et al.*, 2003), and loss of function mutations in the genes of FGFR2 or the FGF-10 ligand give rise to lacrimo-auriculo-dento-digital syndrome (Rohmann *et al.*, 2006).

Met and Ron

Met and Ron RTKs each consists of a Sema domain, a PSI domain and 4 Ig domains extracellularly; the receptors are cleaved to generate α - and β -chain heterodimers. The intracellular part with the kinase domain has a rather short C-terminal tail (Trusolino *et al.*, 2010). Their ligands, HGF/SF and MST1, respectively, are rather large molecules consisting of four N-terminal kringle domains and a C-terminal serine protease homology domain that lacks proteolytic activity.

During embryonal development, Met is essential for the growth, survival and migration of hepatocytes, placental trophoblasts and muscle progenitor cells. Met-null mouse embryos have considerably diminished livers, the placental labyrinth is severely hypomorphic and there is an absence of myogenic precursor cells (Birchmeier and Gherardi, 1998). Met has also an important role in the regeneration of the liver and the kidney after acute or chronic insults (Trusolino *et al.*, 2010). Ron is involved in the development of epithelial, bone

and neuroendocrine tissues (Gaudino *et al.*, 1995) and complete inactivation of Ron in mice leads to early embryonic lethality (Muraoka *et al.*, 1999).

The Eph Family

The Eph family is the largest of the RTK families. It consists of 9 EphA family members that bind to 5 glycosylphosphatidylinositol (GPI)-linked ephrin-A ligands, and 5 EphB members that bind three transmembrane ephrin-B ligands (Pasquale, 2010). Both ephrin-A:s and ephrin-B:s can mediate reversed signaling after binding to Ephs. Structurally, the Eph RTKs are composed of an ephrin binding domain and two leucine-rich domains extracellularly, and a kinase domain and a SAM domain intracellularly.

Eph RTKs have widespread functions in normal physiology (Pasquale, 2008). Eph-ephrin bidirectional signaling is important for communication between neurons, as well as between neurons and glial cells. Eph RTKs and ephrins also have important functions in cell contact-dependent communication in the immune system, for example, in the development of thymocytes into mature T cells in the thymus. Moreover, EphA-ephrin-A interactions are important in the control of insulin secretion in the β -cells, and EphB-ephrin-B interactions in bone development and in intestinal homeostasis (Pasquale, 2008).

The Tie Family

The extracellular parts of each of the two Tie RTKs are characterized by three Ig domains, three EGF domains and three leucine-rich domains (Huang *et al.*, 2010). Tie2 binds the agonistic ligands angiopoietin-1 (Angpt1) and -4; Angpt2, normally acts as a Tie2 antagonist (Maisonpierre *et al.*, 1997), but can under certain conditions have agonistic properties (Yuan *et al.*, 2009). Tie1 has no known ligand, but interacts with Tie2 and negatively regulates its activity (Kim *et al.*, 2006; Milner *et al.*, 2009; Saharinen *et al.*, 2005).

Activation of Tie2 promotes endothelial cell survival and the maintenance of the endothelial barrier (Huang *et al.*, 2010). Activation of Tie2 is also required for the formation of lymph vessels; in this case both Angpt1 and Angpt2 act as Tie2 agonists (Gale *et al.*, 2002).

Tie2-deficient mice die at embryonic day 10.5-12.5 since their vasculature does not develop beyond the primary capillary plexus. In contrast, Tie1-deficient mice die later, after embryonic day 13.5, when their vessels lose their integrity leading to edema and death (Augustin *et al.*, 2009).

The Trk Family

The Trk family consists of three members, i.e., TrkA, B, and C (Skaper, 2012). This RTK family is characterized by an extracellular ligand-binding part consisting of two cysteine-rich motifs, three leucine-rich repeats, and two Ig-like domains. The ligands for Trk receptors are denoted neurotrophins (NT), including NGF, BDNF, NT-3, NT-4, and NT-5. These factors are crucial for neuronal cell survival, growth, and plasticity during development. The different Trk receptors display selective ligand binding; TrkA binds NGF, TrkB binds BDNF, NT-4 as well

as NT-5, and TrkC binds NT-3. In addition, NT-3 can bind TrkA and B, but with lower affinity (Skaper, 2012).

In addition to binding to the Trk family of RTKs, the neurotrophins bind to p75NTR which belongs to the tumor neurosis factor (TNF) receptor family. It has been found that p75NTR assists in the binding of NGF to TrkA. In addition, p75NTR may suppress Trk receptor activation by the 'wrong' neurotrophin (Benedetti *et al.*, 1993). Thus, there is a close functional connection between the Trk and p75NTR receptors. It has been proposed that in the absence of Trk receptor expression, p75NTR can induce apoptosis (Brodeur *et al.*, 2009).

Trk RTKs have important roles during the development of the peripheral nervous system, as illustrated by the phenotypes of Trk knockout mice (Klein *et al.*, 1993, 1994; Smeyne *et al.*, 1994). The observed defects of the different Trk knockout mice display unique as well as overlapping functions in the nervous system of the different receptors. The TrkB knockout is the most severe.

Other RTKs

Besides the receptor families discussed above, there are also other less investigated RTKs. For example, discoidin domain receptors (DDR1 and 2) are widely expressed and are activated in a sustained manner by binding to certain types of collagens (Vogel *et al.*, 2006). Hence DDR1 and 2 are classified as non-integrin collagen receptors. Knockout of DDR genes in mice leads to skeletal and reproductive abnormalities (Fu *et al.*, 2013).

Another RTK that has been found to be relevant in the context of cancer, while its normal physiological role is unclear, is anaplastic lymphoma kinase (ALK) (Hallberg and Palmer, 2013). Ligands for mammalian ALK are heparin-binding growth factors called pleiotrophin and midkine. The kinase domains of ALK, and the related leukocyte tyrosine kinase (LTK), show similarities to the insulin receptor.

Ror1 and Ror2 were long thought to be orphan RTKs. However, their extracellular domains contain frizzled domains in addition to Ig-like, Cys-rich, and kringle domains, and Ror2 has recently been shown to bind Wnt1, 3, and 5 (Green *et al.*, 2008). Ror1 and 2 are expressed during embryonal development and are important for skeletal, respiratory and cardiac development. Moreover, Ror1 is expressed on chronic lymphatic leukemia cells, but not on normal lymphocytes (Daneshmanesh *et al.*, 2008), and on some other tumor types (Zhang *et al.*, 2012).

The Ryk RTK contains a Wnt-inhibitory factor-1 (WIF-1) domain and has, like Ror family members, been shown to bind Wnts, and to be important during neurogenesis, axon guidance, and synaptogenesis (Fradkin *et al.*, 2010).

The Ret tyrosine kinase has an extracellular domain that is related to the cell adhesion molecule cadherin; like cadherins, Ret may require Ca^{2+} binding to be functional (Nozaki *et al.*, 1998). The ligands for Ret are glial cell line-derived neurotrophic factor (GDNF), neurturin, persephin, and artemin (Mulligan, 2014). Ligand binding to Ret requires the expression of a coreceptor family denoted GDNF receptor α . Ret is required for the development of neural and genitourinary tissues.

Muscle-specific kinase (MuSK) is a receptor tyrosine kinase that is expressed on skeletal muscle cells and is important for the connection between muscle cells and motor neurons (Hubbard and Gnanasambandan, 2013). The activation of MuSK requires two proteins; agrin, produced by the motor neuron, interacts with LRP4 expressed on the muscle cells, which enables LRP4 to bind and activate MuSK.

Members of the TAM family of RTKs, which consists of Axl, Tyro3/Sky, and Mer, have important roles in immunoregulation and neurogenesis (Ji *et al.*, 2013; Paccez *et al.*, 2014). Moreover, Axl, the ligand of which is the vitamin K-dependent protein GAS6, has been found to be upregulated in several cancers and its expression correlates to poor prognosis. Axl promotes epithelial-mesenchymal transition and increased invasiveness; in addition, Axl may contribute to chemoresistance of cancers (Gjerdum *et al.*, 2010; Paccez *et al.*, 2014).

RTKs in Disease

RTKs have central roles in processes regulating cell proliferation, survival, and migration; they are frequently deregulated in various diseases, key examples being diabetes and cancer.

Diabetes

Diabetes is a disease that involves defects in insulin signaling. Type-1 diabetes is caused by loss of insulin production by the β -cells in the pancreas, whereas in type-2 diabetes the insulin receptor function is reduced, either by mutations in the receptor or in downstream signaling molecules making the cells resistant to insulin stimulation (Guo, 2014).

Malignancies

In malignancies, RTKs can be deregulated through different mechanisms, including amplification of the genes, activating point mutations or deletions, changed expression of RTKs or their ligands, and translocations creating chimeric proteins containing the RTK kinase domain.

For example, amplification of the ErbB2 gene occurs in 20% of breast carcinomas, overexpression of EGFR occurs in a wide array of carcinomas and a truncated form of EGFR called EGFRvIII has been observed in brain and prostate tumors (Yarden and Pines, 2012), and activating mutations in c-Kit or PDGFR α occur in gastrointestinal stromal tumors (Heinrich *et al.*, 2003). Fusion proteins of RTK kinase domains of the PDGF and FGF receptor families, with different components that have in common that they can oligomerize, occur in hypereosinophilic syndrome and leukemias (Matsumura *et al.*, 2008); fusion proteins with the ALK, Ros, Ret, Trks, FGFRs, Axl, and PDGFR α RTK kinase domains have been observed in lung cancer, colorectal cancer, breast cancer, thyroid cancer, and other cancers (Shaw *et al.*, 2013). In addition, autocrine stimulation of RTKs, as a consequence of production by tumor cells of the corresponding ligand, has been observed in a large number of tumors. All these mechanisms act directly on the cancer cells enhancing their survival and proliferation.

In addition, RTKs also indirectly contribute to tumor growth by regulating angiogenesis. The angiogenesis process is complex and involves many different signaling molecules; VEGF produced by tumor cells has the ability to promote nearby blood vessel endothelial cells to proliferate and migrate toward the tumor (Olsson *et al.*, 2006). Pericytes is another cell type required for normal blood vessel function and a key factor regulating them is PDGF (Lindahl *et al.*, 1997).

RTK Inhibitors in Treatment

The recurrent involvement of overactive RTKs in cancer has stimulated the development of therapeutic RTK antagonists. The clinically used RTK antagonists fall into two major groups; low molecular weight compounds that penetrate the plasma membrane and inhibit the kinase activities of RTKs, and antibodies recognizing the extracellular parts of RTKs, the binding of which interfere with RTK function or cause recruitment of immune cells.

The first tyrosine kinase inhibitor that was introduced into the clinic was imatinib that inhibits the kinase of the Bcr-Abl fusion protein which drives chronic myeloid leukemia. Imatinib also inhibits SCF and PDGF receptor kinases and are therefore also used to treat gastrointestinal stromal tumor (GIST) and other tumors driven by these receptors (Heinrich *et al.*, 2003). A number of other inhibitors have subsequently been developed, including lapatinib, erlotinib and gefitinib against EGF receptor family kinases, which are used to treat, for example, lung cancer (Shawver, 2002), sunitinib which inhibits several kinases including SCFR, PDGFRs, VEGFRs, Flt3, and Ret which is used to treat GIST and renal cell carcinoma (Chow and Eckhardt, 2007), and several other inhibitors.

Monoclonal antibodies that are used clinically include trastuzumab against ErbB2 which is used to treat breast cancer with ErbB2 amplification, cetuximab, and panitumumab against the EGF receptor which are used to treat colorectal cancer and head and neck cancer (Reichert and Valge-Archer, 2007). In addition, a monoclonal antibody against VEGF, bevacizumab, is used for anti-angiogenic therapy.

Unfortunately, drug resistance very often develops after some time of anti-RTK treatment. Mechanisms involve the appearance of RTK mutants that are insensitive to the inhibitor, activation of parallel signaling pathways that take over, or activation of membrane transporters that pump out the drug from the tumor cell (Holohan *et al.*, 2013). Anti-RTK treatment of malignancies therefore most likely need to be combined with other types of treatment in order to achieve complete tumor remission.

Glossary

Cysteine knot fold A protein structural motif containing three disulfide bridges. Two of the disulfide bridges create a polypeptide loop through which a third disulfide bond passes, forming a structurally stable mechanically interlocked molecular substructure known as a rotaxane.

The cysteine knot fold occurs in many proteins across a wide range of species and include the growth factor cysteine knot, cyclotides, and the inhibitor cysteine knot.

Elbow The hinge-like region that exists between two adjacent FnIII domains in the same protein chain. The shape is reminiscent of an elbow, hence the name.

Fibronectin Type III (FnIII) domains FnIII domains belong to the immunoglobulin (Ig)-like protein family and adopt one of the most common extracellular protein folds. These domains typically consist of two β -sheets, each containing at least seven antiparallel β -strands, packed against each other in an arrangement known as a β -sandwich.

Immunoglobulin (Ig)-like domains Immunoglobulin (Ig) and Ig-like proteins are modular and their domains have been classified into four types; V-set, C1-set, C2-set, and I-set. Each domain consists of a β -sandwich structure, with differing numbers of β -strands in each of the β -sheets making up the β -sandwich.

Leucine-rich repeats As the name suggests, the leucine-rich repeat (LRR) is a repetitive sequence pattern rich in leucines and approximately 20–30 amino acids in length. Two or more consecutive LRRs can form curved linear

solenoid structures that are able to participate in protein–protein interactions.

Pseudokinase domains Traditionally defined as a kinase domain that is incapable of phosphoryl group transfer due to an incomplete catalytic motif. Pseudokinases are now known to act as signal transducers and are able to allosterically activate protein kinases.

SEFIR domain The name stands for 'similar expression to fibroblast-growth factor genes and IL-17R.' These signaling domains consist of six α -helices wrapped around a five-stranded parallel β -sheet core.

Sushi domain Sushi domains are based on a β -sandwich structure, one face contains three β -strands hydrogen-bonded to form a triple-stranded central region and the opposite face is formed by two separate β -strands. These exist in a wide variety of adhesion and complement proteins; are also known as short consensus repeats (SCR) and complement control protein (CCP) modules.

The Toll/IL-1 receptor signaling domain The Toll/IL-1 receptor (TIR) signaling domain was previously known as the Toll/IL-1 resistance domain and consists of three conserved sequence motifs designated box 1 (FDFAFISY), box 2 (GYKLC-RD-PG), and box 3 (a conserved W surrounded by basic residues). Boxes 1 and 2 are thought to be involved in the binding of signaling proteins, whereas it has been suggested that the main function of box 3 is directing receptor localization. The TIR domains of human Toll receptor 1 (TLR1) and TLR2 contain a five-stranded parallel β -sheet core surrounded by five α -helices.

Introduction

Cytokines are responsible for a wide range of biological processes, particularly in the survival, proliferation, differentiation, and functional activity of many types of cells. Abnormal cytokine levels or aberrations in their signaling pathways can lead to a variety of diseases, including cancers and inflammatory conditions reflecting their importance in normal hematopoiesis and immunity.

On the basis of common structural features, cytokine receptors are grouped into six major families: type I cytokine receptors, type II cytokine receptors, TNF receptors, IL-1 receptors, tyrosine kinase receptors, and chemokine receptors. The type I

(hematopoietic) cytokine receptors are characterized by having cytokine-binding modules (CBM) consisting of two adjacent β -sheet sandwich fibronectin type III (FnIII) domains. Two distinctive features of the CBM are, firstly, four highly conserved cysteine residues in the N-terminal FnIII domain and, secondly, a Trp-Ser-X-Trp-Ser motif (also known as the 'WSXWS' box, where X is a nonconserved residue) in the C-terminal FnIII domain. Both features are believed to be important for maintaining the structural integrity of the extracellular region to facilitate ligand-receptor interactions (Bazan, 1990a; Kernebeck *et al.*, 1999). The type I cytokine receptors also have sequence motifs in their cytoplasmic domains, called box 1 and box 2, that are responsible for receptor interaction with protein

partners. The type II (non-hematopoietic) cytokine receptors are similar to type I cytokine receptors except they do not possess the signature WSXWS motif.

Activation of the human growth hormone (hGH) and cytokine receptors was originally proposed to occur via homo- or heterodimerization (Weiss and Schlessinger, 1998). However, subsequent molecular and structural studies have extended this model to include the formation of higher order receptor oligomers as well as ligand-induced conformational changes in preformed receptor dimers and oligomers (Brown *et al.*, 2005; de Vos *et al.*, 1992; Livnah *et al.*, 1999; Figure 1). Receptor oligomerization or ligand-induced preformed dimer conformational change is thought to initiate activation of kinases (such as the Janus kinase JAK2 in the case of archetypical human growth hormone receptor (hGHR)), that are normally bound to the cytoplasmic tails of the resting receptor chains, by bringing the kinase molecules close enough to each other thus allowing transphosphorylation of the receptor cytoplasmic tails on specific tyrosine residues (Figure 1). This in turn creates docking sites for signaling and adaptor molecules such as STAT (signal transducer and activator of transcription) and the Src homology-2 containing protein Shc respectively, leading to distinct functions and the further building and assembling of an active signalosome.

Recent years have seen a steady stream of new cytokine receptor crystal structures including those that are activated by GM-CSF, Type I interferon, and a variety of interleukins. Here we give a brief overview of the cytokine family of receptors with a particular focus on how structural biology has shed light on their mechanism of signaling with implications for the development of new drugs to treat a variety of inflammatory diseases and cancer.

hGHR and Related Receptors

hGHR is the paradigm for understanding cytokine recognition and signaling of much of the cytokine superfamily (Figures 1 and 2). The hGHR extracellular region consists of the minimal structural elements of a type I cytokine receptor comprising a tandem set of FnIII domains (a single CBM), a single transmembrane (TM) domain, and a cytoplasmic tail (Figure 1). Two possible cytokine-binding pathways leading to receptor activation and downstream signaling have been put forward. The first involves binding of the four α -helical bundle hormone to the elbow between the two FnIII domains of one receptor chain, called Site 1, to form a binary complex (Figure 1, far left). The hormone in the binary complex is then recognized by a second receptor chain at its elbow, via a Site 2 interface. The two receptors come together at the membrane-proximal region resulting in a Site 3 interaction. The second pathway involves the hormone binding directly to a preformed receptor dimer (Figure 1, far right). A striking feature of this recognition process is how a single ligand can be recognized in two different ways by the same receptor chain.

For hGHR and other related cytokine receptors such as the erythropoietin (EPO), prolactin (PRL), and thrombopoietin (TPO) receptors, the hormone-induced model has recently been superseded with the demonstration that these receptors exist largely as inactive dimers in the absence of ligand (Brown *et al.*, 2012; Hercus *et al.*, 2009; Hiwase *et al.*, 2010; Lopez *et al.*, 2010; Wang *et al.*, 2009; Wells and de Vos, 1996). It was found that the TM domains of these single-pass cytokine receptors play an important role in their constitutive dimerization and the existence of inactive dimers implies that a specific ligand-induced conformational change is required for signal transmission to the associated cytoplasmic JAK2

Figure 1 Human growth hormone (hGH) signaling as a paradigm for the cytokine receptor superfamily. A cartoon representation of hGH receptors (hGHR, in blue) shown bound to a lipid cell membrane. Domains D1 and D2 of hGHR define the cytokine-binding motif (CBM). Transmembrane (TM) domains are represented as blue rectangles. Red arrows indicate binding sites defined in the text. On the left hand side of the panel hGH (yellow colored cartoon) is shown binding first to a single receptor subunit (Site 1), which then induces receptor dimerization (Sites 2 and 3). The signaling complex is then activated via intracellular transphosphorylation of associated JAK molecules (represented as red hexagons) and cytoplasmic tails (brown sticks). From the right hand side of the panel moving left, a preformed symmetrical hGHR dimer is shown, which then undergoes conformational change upon ligand binding to activate the asymmetric complex. (PDB ID: 3HHR).

2014). This mechanism leads to removal of the pseudokinase domain from the kinase domain of the partner JAK2 and pairing of the two kinase domains, facilitating trans-activation (Figure 1).

The simple homodimeric receptor system seen in hGHR has evolved to much more complicated heteromeric systems, often involving shared receptors, but clear structural analogies in terms of conserved architectures and rules of receptor recognition can still be traced back to hGHR in spite of low (<20%) sequence identities between cytokines and between receptor chains in the same cytokine family (Figure 2). Such observations highlight the critical roles that crystallographic structural studies have played in unmasking unexpected similarities between proteins with highly divergent primary structures and disparate biological functions.

Beta Common Receptors

The β common (βc) family of cytokines consists of granulocyte-macrophage colony-stimulating factor (GM-CSF) and interleukins IL-3 and IL-5 (Figure 2). They are produced by activated T cells (and in the case of GM-CSF also by many other cell types) to regulate the survival, proliferation, differentiation, and functional activation of hematopoietic cells after infection or blood cell loss (Codarri *et al.*, 2011). The targets of GM-CSF are myeloid hemopoietic progenitor cells and mature cells such as neutrophils and macrophages (Burmester *et al.*, 2014; Hercus *et al.*, 2013). IL-3 is important for the production and function of hemopoietic stem cells, mast cells, and basophils (Dahl *et al.*, 2004; Lantz *et al.*, 1998), and IL-5 selectively stimulates the production and activation of eosinophils (Lopez *et al.*, 1988).

Recent evidence suggests that this family of cytokines plays a key role in cancer. Both IL-3 and GM-CSF contribute to the development and metastasis of solid tumors (Korpelainen *et al.*, 1993; Pylayeva-Gupta *et al.*, 2012; Su *et al.*, 2014). Intriguingly, the α -subunit of the IL-3 receptor (IL-3R α) is overexpressed on the surface of leukemic stem cells and primary blasts of patients with acute myelogenous leukemia (AML) and this correlates with poor prognosis (Jin *et al.*, 2009; Jordan *et al.*, 2000; Testa *et al.*, 2002). This observation has led to several strategies that target the IL-3R α such as antibodies that block IL-3 function and mediate killing of AML cells overexpressing IL-3R α (Busfield *et al.*, 2014; Gill *et al.*, 2014; Jin *et al.*, 2009; Nievergall *et al.*, 2014) by immune mechanisms.

GM-CSF, IL-3 and IL-5 are glycoproteins with architectures similar to that of hGH (Figures 1 and 2) as they are largely composed of four short antiparallel α -helices (Hercus *et al.*, 2013). While there are minor structural differences between GM-CSF and IL-3 (Feng *et al.*, 1996; Rozwarski *et al.*, 1996), IL-5 is distinct as it exists as a homodimer (Milburn *et al.*, 1993).

GM-CSF, IL-3, and IL-5 bind heterodimeric receptors composed of a type I cytokine-specific α -subunit and a common β -subunit (βc), which is shared by all three receptors and is the major signaling subunit. Unlike hGHR, the receptor α -subunits contain three FnIII domains: the N-terminal domain (D1), D2, and the membrane-proximal domain D3; D2-D3 comprise the CBM. The three FnIII domains wrap around the cytokine, as revealed by the crystal structure of the IL-5R α binary complex (Kusano *et al.*, 2012; Patino *et al.*, 2011). Apart from the IL-5R α binary complex structure, there is a partial crystal structure of the GMR α ternary complex (Hansen *et al.*, 2008), and a complete structure of IL-3R α bound to a blocking antibody (Broughton *et al.*, 2014). The crystal structure of βc (Figure 2) showed that it is an intertwined dimer that forms an arch spanning from the TM domain of one βc subunit to the TM domain of the second βc subunit (Carr *et al.*, 2001). Each of the βc monomers consists of four FnIII domains, designated D1 (N-terminal domain) through to D4 (membrane-proximal domain).

The GM-CSF ternary complex crystal structure revealed how the receptor is activated upon cytokine binding (Hansen *et al.*, 2008). Initially, GM-CSF binds to the elbow region between D2 and D3 of GMR α (analogous to Site 1 in Figure 1) to form a low-affinity binary complex ($K_d \sim 10$ nM) (Hercus *et al.*, 1994). Then, βc is recruited to the binary complex through interactions with GM-CSF and D3 of GMR α , analogous to Sites 2 and 3 respectively in Figure 1. Site 2 in βc uses a chimeric interaction surface composed of residues from D1 of one monomer and from D4 of the second βc monomer (Hansen *et al.*, 2008). This arrangement is unique in the type I cytokine receptor superfamily. The resulting ternary complex includes a βc homodimer, two GM-CSF molecules, and two α -subunits and converts the binding of cytokine to high affinity ($K_d = 100$ pM) (Hansen *et al.*, 2008).

Interestingly, the crystal lattice of the GM-CSF ternary receptor complex revealed a unique higher order dodecameric complex composed of two hexamers associating through the membrane-proximal D3 of GMR α and D4 of βc of each hexamer (Site 4). Formation of the dodecamer brings the intracellular βc domains into close proximity (~ 10 Å), which allows for JAK2 transphosphorylation and receptor activation (Broxmeyer *et al.*, 2012; Hansen *et al.*, 2008). Activated JAK2 phosphorylates tyrosine residues on βc (Guthridge *et al.*, 2004), which then act as docking sites for proteins that lead to the activation of JAK2/STAT5, Ras/Raf/MAPK, and PI3-kinase/Akt pathways (Ramshaw *et al.*, 2007). The IL-3 and IL-5 receptors are also predicted to form higher order complexes similar to that identified for the GM-CSF receptors (Dey *et al.*, 2009; Patino *et al.*, 2011; Zaks-Zilberman *et al.*, 2008).

Figure 2 Family tree of human cytokines and their receptors. Cytokines and their receptors are represented as cartoons and colored according to common features and structural motifs. The associated activating cytokines with known three-dimensional structures are shown with their respective receptor. For clarity, entire assembled receptors or partial structures are not shown. Some cytokines may be commonly assigned to more than one group. IFNLR1, IFN λ 1, IFN λ 2, and IFN λ 3 are also known as IL-28R α , IL-28 α , IL-28 β , and IL-29, respectively. The cytokines IL-36 α , IL-36 β , and IL-36 γ have not been included under the IL-1-like branch due to space limits. Similarly, thrombopoietin (TPO) and its receptor have not been included under the homodimeric branch due to space restrictions. There are currently no three-dimensional structures for the IL-36 α , IL-36 β , IL-36 γ and TPO cytokines or the TPO receptor. CT-1, cardiotrophin-1; CLC, cardiotrophin-like cytokine; CNTF, ciliary neurotrophic factor; EPO, erythropoietin; gp130, glycoprotein 130; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; GH, growth hormone; IFN, interferon; IL, interleukin; PRL, prolactin; LIF, leukemia inhibitory factor; OSM, oncostatin-M; TLSP, thymic stromal lymphopoietin (PDB IDs are: 2B51, 4GS7, 3BPO, 3BPL, 3DI2, 3TGX, 3SE4, 1FG9, 1AU1, 1RH2, 3S9D, 2GYS, 3CXE, 3QT2, 4JZJ, 1JLI, 3LB6, 3L5H, 1ALU, 111R, 1N26, 2KUM, 1EVS, 1EMR, 3EOG, 1F45, 3D87, 4DOH, 1N1F, 1J7V, 3LQM, 3DLQ, 3OG4, 4HSA, 4JPY, 1ICW, 1I16, 4DKC, 3UF2, 4DEP, 2L5X, 2VXT, 4KC3, 3G9V, 1EER, 3D48, 1CD9, 3HHR, 3HHH, 2Z3Q, 1P9M, 1X6D, 1AX8, 3O4O, 3V6O, and 1CNT).

Gamma Common Receptors

The gamma common (γ c) family of cytokines includes interleukins IL-2, IL-4, IL-7, IL-9, IL-15, IL-21, and thymic stromal lymphopoietin (TSLP) (Wang *et al.*, 2009). These cytokines regulate the development, proliferation, and homeostasis of B, T, and natural killer (NK) cells of the immune system (Leonard *et al.*, 1994a; Rochman *et al.*, 2009). The biological importance of the γ c receptor is evidenced by the fact that mutations in this receptor or its associated JAKs abolish functions of all γ c-dependent cytokines and causes X-linked severe combined immunodeficiency diseases (SCID) (Leonard *et al.*, 1994b). The γ c-dependent cytokines belong to the type I cytokine superfamily and they are functional monomers that adopt the classical left-handed four-helix bundle structure (Figures 1 and 2). Crystal structures of many γ c-dependent cytokine:receptor complexes have been solved and they are discussed below.

IL-2/IL-15 Receptors

IL-2 and IL-15 are key regulators of lymphocyte homeostasis and function. IL-2 is an autocrine/paracrine factor produced primarily by antigen-activated T cells and it was initially pursued as a therapeutic agent for patients with metastatic renal cell carcinoma and metastatic melanoma; however, severe toxicities associated with high-dose IL-2-based therapies have limited its clinical use (Levin *et al.*, 2012; Schwartzentruber *et al.*, 2011). IL-15 is produced by activated monocytes and dendritic cells and has been implicated in inflammatory diseases such as rheumatoid arthritis (Mattei *et al.*, 2001; Nelson and Willerford, 1998; Votavova *et al.*, 2014; Waldmann and Tagaya, 1999).

Both IL-2 and IL-15 signal through heterotrimeric 'high affinity' complexes consisting of a selective IL-2R α or IL-15R α receptor and two common receptors, IL-2R β and γ c (Chirifu *et al.*, 2007; Kono *et al.*, 1993; Nakamura *et al.*, 1994; Olsen *et al.*, 2007; Rickert *et al.*, 2005; Stauber *et al.*, 2006). The IL-2R α /15R α receptors are comprised of two sushi domains and upon binding to their respective cytokines form a stable binary complex that lacks signaling activity. This binary complex is then recruited by the signaling subunits IL-2R β and γ c to form an active signaling complex. Crystal structures of the quaternary complexes of both IL-2 and IL-15 have been determined to reveal a striking similarity in the membrane-proximal or 'signaling ends' of the cytokine receptors (Ring *et al.*, 2012). The shared signaling subunits, IL-2R β and γ c, have the same domain architecture as hGHR and the cytokine binds in a similar fashion as hGH (Figure 1). Since the assembly of the two cytokine heterotrimeric receptors is almost identical, differences in signaling is attributed to: distinct expression patterns of the IL-2R α /15R α receptors; differences in receptor binding kinetics; the presentation mode of the cytokine, i.e., *cis* versus *trans*, by the IL-2R α /15R α receptors to the common receptor subunits and the presence of additional signals such as those from the T-cell antigen receptor (Rickert *et al.*, 2005; Ring *et al.*, 2012; Stauber *et al.*, 2006).

IL-4/IL-13 Receptors

While IL-13 is not a γ c-dependent cytokine, it does share the IL-4 specific receptor, IL-4R α , and hence it will also be discussed here.

Like the γ c-dependent cytokines, IL-13 adopts the classical left-handed four-helix bundle structure observed for hGH (Figures 1 and 2) (Lupardus *et al.*, 2010). The cytokines IL-4 and IL-13 are produced by activated T helper type 2 (TH2) cells, mast cells and basophils (Chomarat and Banchereau, 1998; Nelms *et al.*, 1999; Wynn, 2003). Deregulation of the IL-4 and IL-13-mediated responses has been implicated in the pathology of asthma and allergic diseases (Barnes, 2002; Wills-Karp, 2004).

IL-4 binds to the IL-4R α receptor with high affinity (forming a binary complex), which then leads to receptor dimerization with either the γ c chain to form a type I receptor complex (in hematopoietic cells) or with the IL-13R α 1 receptor to form a type II receptor complex (in non-hematopoietic cells) (Arima *et al.*, 2005; Kelly-Welch *et al.*, 2003; Mueller *et al.*, 2002). The IL-4R α receptor shares the same domain architecture as hGHR (Figure 1), whereas IL-13R α 1 contains an additional membrane-distal FnIII domain (D1) set at $\sim 100^\circ$ to the middle FnIII domain (D2) so that the extracellular region adopts an overall zig-zag conformation, analogous to the domain architecture of IL-5R α (Figure 2; LaPorte *et al.*, 2008). IL-4 interacts with IL-4R α and γ c in an analogous fashion to hGH (Figure 1); whereas in the IL-4: IL-4R α :IL-13R α 1 ternary complex the N-terminal IL-13R α 1 FnIII domain (D1) folds down over the cytokine in a manner that has been likened to a wrench (IL-13R α 1) fitting around a nut (cytokine) (Patino *et al.*, 2011). IL-13 can form an analogous type II receptor complex by binding to both IL-13R α 1 and IL-4R α . Differential responses to IL-4 and IL-13 cytokines are achieved by 'tuning' the respective affinities of the cytokines for the IL-13R α 1 receptor (Andrews *et al.*, 2009; Ito *et al.*, 2009).

IL-13R α 2 is a high affinity receptor of IL-13 which serves as a decoy binding protein due to its short intracellular domains that lack JAK interaction motifs (Andrews *et al.*, 2009; Wood *et al.*, 2003). The crystal structure of the IL-13:IL-13R α 2 binary complex revealed that the receptor adopts a very similar fold to IL-13R α 1, but utilizes peripheral residues unused in the IL-13: IL-13R α 1 complex to generate a larger complementary interface for IL-13 binding (Lupardus *et al.*, 2010). Interestingly, IL-13R α 2 has been reported to be significantly up-regulated in a number of human cancers (Kioi *et al.*, 2006; Mintz *et al.*, 2002) making it a potential target for tumor-specific therapeutics (Kahlon *et al.*, 2004).

IL-7/TSLP Receptors

IL-7 and its receptors play an important role in the development and maintenance of B and T cells and extracellular matrix remodeling. Aberrant IL-7 signaling has been shown to lead to diseases such as cancer, heart disease, and allergic rhinitis upon overstimulation and SCID when understimulated (Kovanen and Leonard, 2004; Lundström *et al.*, 2012; Rochman *et al.*, 2009). IL-7 receptors signal via the JAK/STAT, PI3-kinase/Akt, and Src pathways (Mazzucchelli and Durum, 2007).

Like the IL-4R α , IL-2R β , and γ c receptors, IL-7R α has the same domain architecture as hGHR (Figure 1; McElroy *et al.*, 2012). In the crystal structure of the IL-7:IL-7R α binary complex, the interactions between the two proteins are generally more hydrophobic and nonspecific than those observed in

other γ c-dependent cytokine receptor complexes (McElroy *et al.*, 2012). Surface plasmon resonance studies of the IL-7:IL-7R α binary complex revealed that N-glycosylation of the receptor chain is critically important for high affinity binding, in stark contrast to the other members of the γ c receptor family (McElroy *et al.*, 2009; Walsh, 2012; Wickham and Walsh, 2007). It has been speculated that glycosylation may influence the engagement of IL-7 with its receptor by affecting the overall electrostatic potential of the receptor chain or altering the conformational states of the receptor (McElroy *et al.*, 2009). IL-7R α can form homodimers at the cell surface, with the C-termini of the extracellular domains separated by ~ 110 Å, but they do not activate downstream signaling (McElroy *et al.*, 2012). In addition to interacting with IL-7, IL-7R α also binds to TSLP and the TSLP receptor (TSLPR) (Wang *et al.*, 2013; Ziegler and Artis, 2010). TSLP is expressed by epithelial cells in the skin, lung, thymus, and intestine and plays a key role in intestinal immune homeostasis and in mediating allergic inflammatory processes, including those related to asthma and atopic dermatitis (Roan *et al.*, 2012; Zhang and Zhou, 2012).

Shared Glycoprotein 130 Receptors

The IL-6 cytokine family comprises the archetypal family member IL-6, along with IL-11, IL-27, IL-31, leukemia inhibitory factor (LIF), oncostatin-M (OSM), ciliary neurotrophic factor (CNTF), cardiotrophin-1 (CT-1), cardiotrophin-like cytokine (CLC), and neuropoietin (NPN). A unifying feature of these cytokines is their similar tertiary structure, which despite a lack of sequence homology, is made up of a conserved four α -helical bundle analogous to hGH (Figures 1 and 2; Bazan, 1990b). Another hallmark of this family of cytokines, with the exception of IL-31 (Dillon *et al.*, 2004), is their usage of the ubiquitously expressed shared signal-transducing receptor β -subunit, glycoprotein 130 (gp130) (Heinrich *et al.*, 2003), to drive their collective biological activities (e.g. cell proliferation, survival, functional maturation, and differentiation).

The gp130 signaling subunit belongs to the type I 'tall' cytokine receptor family; the 'tall' cytokine receptor family contains additional IL-6 family cytokine-specific β -receptors for LIF (LIFR), OSM (OSMR), IL-27 (IL-27R/WSX-1), and IL-31 (IL-31RA, also known as gp130-like protein (GPL)), as well as the β -receptors for IL-12 (IL-12R β 2), GM-CSF (β c), and leptin (LEPR) (Skiniotis *et al.*, 2005). IL-6 and IL-11 signal via gp130 homodimers whereas all other family members employ heterodimers of gp130 with their respective β -receptor, for example, LIFR, OSMR, and IL-27R (Figure 2; Heinrich *et al.*, 2003). The exception to this rule is IL-31, which utilizes a heterodimer of IL-31RA and OSMR (Dillon *et al.*, 2004). The extracellular region of these receptors contains numerous immunoglobulin (Ig)-like and FnIII-like domains; for example, gp130 consists of six structural domains (D1 through to D6) classified as N-terminal Ig-like domain (D1), two adjacent FnIII domains within the CBM (D2-D3) and three membrane-proximal FnIII domains (D4-D6) (Bazan, 1990a). Despite the lack of intrinsic tyrosine kinase activity, the membrane-proximal region of the cytoplasmic domain of gp130 and its related

cytokine-specific β -subunits (e.g. LIFR, OSMR) also contain a conserved proline-rich motif ('box 1' motif), which via mutagenesis has been demonstrated to be critical for the constitutive association and ligand-induced activation of members of the JAK family of non-receptor tyrosine kinases (JAK1, JAK2, and TYK2) (Lupardus *et al.*, 2011; Murakami *et al.*, 1991).

Among the IL-6 cytokine family, assembly of gp130-containing receptor complexes is best characterized for IL-6. IL-6, and in an analogous manner IL-11, first bind with high affinity to its cognate α -subunit (IL-6R α , IL-11R α), itself comprising an extracellular Ig-like N-terminal domain (D1) adjacent to a CBM (D2-D3), a TM domain, and a short cytoplasmic domain that does not have any signaling potential (Yawata *et al.*, 1993). In addition to this conventional mode of receptor assembly, it is worth noting two other mechanisms employed by IL-6 family cytokines, both of which involve IL-6R α , to promote their vast pleiotropic and/or redundant biological properties. Firstly, in a process called 'trans-signaling,' a naturally occurring soluble form of IL-6R α , which upon its production via either protease-induced shedding or alternative mRNA splicing, can bind IL-6 to facilitate association with gp130, thus providing IL-6 with an avenue to activate gp130 signaling in a vast array of cell types that do not normally express the membrane-bound IL-6R α (Chalaris *et al.*, 2011). Secondly, IL-6R α is also used by CNTF to induce LIFR: gp130 heterodimers (Schuster *et al.*, 2003), which suggests that in certain situations cells can become responsive to CNTF even in the absence of the CNTF ligand-binding α -subunit CNTFR. Despite these variations, a common outcome during the ligand-induced assembly of gp130-containing receptor complexes is the activation of the receptor-associated JAKs, which tyrosine phosphorylate gp130 (and the associated cytokine-specific β -subunits) to facilitate the subsequent activation of downstream signaling molecules, such as STAT, extracellular signal regulated kinase (ERK), MAPK, and PI3-kinase (Heinrich *et al.*, 2003).

Insights into the mechanisms by which ligand-bound, gp130-containing receptor complexes are formed have evolved greatly over the last couple of decades, from earlier molecular modeling and site-directed mutagenesis studies to more recent and advanced experimental approaches combining NMR spectroscopy, low resolution electron microscopy and crystallography to generate high resolution crystal structures (Boulanger *et al.*, 2003a; Chow *et al.*, 2001; Horsten *et al.*, 1997; Kalai *et al.*, 1997; Kernebeck *et al.*, 1999; Lupardus *et al.*, 2011; Schwantner *et al.*, 2004; Xu *et al.*, 2010; Yawata *et al.*, 1993). Importantly, the crystal structure for the IL-6-bound receptor complex revealed a hexameric IL-6:IL-6R α :gp130 complex with 2:2:2 stoichiometry, thus providing formal evidence for the presence of gp130 dimers (Boulanger *et al.*, 2003b). Furthermore, comparative analyses of the structure of the extracellular region of gp130 in a ligand-bound versus ligand-free state suggested that ligand binding induces only subtle structural changes in gp130 that are required to activate intracellular signaling cascades (Xu *et al.*, 2010). Collectively, the detailed structural information obtained on individual receptor subunits has further defined critical amino acids for subunit-subunit and ligand-subunit interactions during receptor assembly, which is important for the design of small peptide and chemical inhibitory molecules for potential use as therapeutics to combat the myriad of inflammatory and autoimmune diseases, as well as cancers, in

which the IL-6 family cytokines are implicated (Mansell and Jenkins, 2013).

IL-1 Receptors

IL-1 was the first cytokine identified (Dinarello, 2013; Dinarello *et al.*, 1977) and is closely linked to innate inflammatory and immune responses. The family of IL-1 ligands has now expanded to include IL-1 α , IL-1 β , IL-18, IL-33, IL-36 α , IL-36 β , and IL-36 γ , which are related through receptor recognition and structure (Figure 2), and the signal transduction pathways emanating from their respective receptors (Boraschi and Tagliabue, 2013; Garlanda *et al.*, 2013). IL-1 family members play a crucial role in maintaining tissue integrity, maturing the adaptive immune response, and maintaining homeostasis (Arend *et al.*, 2008), largely due to receptor-mediated activation of the key transcription factor, NF- κ B. Here we will focus on the prototypic pyrogenic cytokines IL-1 α and IL-1 β and their receptor complexes.

A characteristic feature of the IL-1 receptor (IL-1R) family is the cytosolic Toll/IL-1 receptor domain (TIR, originally termed Toll/IL-1 resistance) (Gay and Keith, 1991), common to both IL-1 family receptors and Toll-like receptors (TLR). A key structural difference, however, is the extracellular ligand-binding domain; IL-1Rs contain Ig domains, while TLRs consist of leucine-rich repeats (LRRs) that define ligand specificity. Ligand-induced receptor dimerization provokes homotypic dimerization of the cytosolic TIR domains, causing recruitment of the protein encoded by myeloid differentiation primary response gene 88 (MyD88) to the receptor complex. Recruitment of MyD88 initiates signal transduction via activation of IL-1R-associated kinase (IRAK)-1, IRAK-4, and tumor necrosis factor receptor-associated factor (TRAF)-6, leading to activation of the I κ B kinase signalosome, which instigates NF- κ B nuclear translocation and gene transcription. Activation of NF- κ B induces inflammation and amplification of the immune response (Pahl, 1999), which requires tight regulation, as excessive activation of NF- κ B by TIR-mediated signaling is now known to be associated with tissue and organ damage and is an underlying pathology in multiple diseases (Dinarello *et al.*, 2012; O'Neill *et al.*, 2009). As such, there is considerable interest in understanding the IL-1R complex with an aim to therapeutically targeting it to alleviate inflammation.

IL-1R1

The IL-1 receptor type 1 (IL-1R1) is the high affinity membrane-bound receptor that binds IL-1 α and IL-1 β . This was the first identified IL-1 receptor and it comprises an extracellular domain of three Ig-like domains and a cytosolic TIR domain. Resolving the IL-1R1 crystal structure to 2.5 Å resolution demonstrated that the two N-terminal Ig domains (D1 and D2) of IL-1R1 are configured in a rigid structure due to an interdomain disulfide bond, while the D3 membrane-proximal Ig domain is flexible (Figure 2; Vigers *et al.*, 1997). Binding of IL-1 β demonstrates that IL-1R1 wraps around the cytokine, contacting via two surface patches; a predominate patch in the groove between D1 and D2 and a smaller region on the side of D3. It is presumed, though not defined as yet,

that IL-1 α binds in a similar fashion due to homology and binding affinity (approximately 0.1–1.0 nM for both interleukins) (Symons *et al.*, 1995). While IL-1R1 binds its antagonistic ligand IL-1 α with similar high affinity as IL-1 α / β , the binding interface is different. While IL-1 α binds the large patch on IL-1R1 D1 and D2, it fails to bind the smaller patch on D3, resulting in only a partial wrapping of the receptor around IL-1 α , and the receptor structure being more open and extended than the IL-1 β :IL-1R1 complex (Schreuder *et al.*, 1997). The arrangement thus fails to recruit IL-1R3, whose involvement is described below, and the complex cannot induce signal transduction.

IL-1R1 can also undergo metalloproteinase-mediated shedding of the extracellular Ig domains (Elzinga *et al.*, 2009; Twomey *et al.*, 2009), producing a soluble receptor (sIL-1R1) that can act as a decoy receptor to prevent excessive IL-1-induced membrane-proximal signaling. However, sIL-1R1 can also sequester IL-1 α , potentially offsetting the inhibitory capacity of IL-1 α (Burger *et al.*, 1995; Symons *et al.*, 1995). Genetic deletion or ablation of IL-1 α causes severe systemic and local inflammation, further highlighting its role in balancing IL-1R-mediated inflammation (Masters *et al.*, 2009).

IL-1R2

Similar to IL-1R1, IL-1R2 consists of three extracellular Ig-like domains and is able to bind IL-1; however, because it lacks a cytoplasmic TIR domain, it acts as a decoy receptor (Colotta *et al.*, 1994; McMahan *et al.*, 1991). Following IL-1 binding, IL-1R2 can recruit IL-1R3; however, as IL-1R2 does not contain a TIR domain, a nonfunctional receptor complex is formed that cannot recruit MyD88.

Interestingly, while IL-1R2 can bind IL-1 β at similar affinity as IL-1R1 (2–5 nM) and has a five- to ten-fold lower affinity for IL-1 α than IL-1R1, it recognizes IL-1 α poorly with ~1000-fold lower affinity (Symons *et al.*, 1995). IL-1R2 can also be cleaved proteolytically from the membrane surface generating either a 60 kDa or 45 kDa soluble fragment (sIL-1R2) that can bind IL-1 (Lorenzen *et al.*, 2012; Orlando *et al.*, 1997). sIL-1R2 is able to bind pro-IL-1 β (Symons *et al.*, 1995), the inactive IL-1 β precursor, indicating that sIL-1R2 appears to recognize the presence of pro-IL-1 β from necrotic cells. sIL-1R2 is also able to engage soluble IL-1R3 (see below), which increases its binding affinity for IL-1 about 100-fold, a mechanism that appears to represent a further way of regulating IL-1 availability and its downstream effects on the inflammatory response (Smith *et al.*, 2003). An intracellular form of IL-1R2 has also been described to bind cytosolic IL-1 α , which protects it from maturation by proteolytic processing.

IL-1R3

IL-1R3 is the most promiscuous of the IL-1R family, not only forming a high affinity complex with IL-1R1 and IL-1R2, but also acting as an accessory signaling receptor with IL-1R4 and IL-1R6 to form agonist receptor complexes for IL-33 and IL-36 respectively (reviewed in Boraschi and Tagliabue, 2013; Garlanda *et al.*, 2013). Consistent with IL-1R1, IL-1R3 consists of three Ig-like extracellular domains linked to the cytosolic

TIR domain via a single-pass TM domain. While IL-1R3 does not bind IL-1 directly, it is necessary to form an active signaling complex with IL-1R1 (hence its previous name IL-1R Accessory Protein). An IL-1R1 interaction with IL-1R3 via the extracellular Ig-like domains causes cytosolic TIR:TIR association to initiate active downstream signaling to NF- κ B.

In silico and crystal structure elucidation of IL-1R3 in complex with IL-1 β and IL-1R1 (and IL-1R2) has demonstrated that IL-1R3 engages IL-1R1 on the reverse side of ligand binding, interacting with D2 and D3 of IL-1R1, but having little to no contact with IL-1 itself (Boraschi *et al.*, 1995; Casadio *et al.*, 2001). It was also demonstrated that IL-1R3 engagement with IL-1 α :IL-1R1 complexes only facilitated interaction with IL-1R1 D2, resulting in the formation of an unstable and hence inactive, receptor complex, which supports earlier experimental findings (Wang *et al.*, 2010). As with other IL-1R family members, alternative splicing produces a soluble IL-1R3 (sIL-1R3), which has been hypothesized to act as a further decoy receptor to negatively regulate IL-1 function (Greenfeder *et al.*, 1995). There are four other alternatively spliced variants of IL-1R3 which are produced under a variety of circumstances and expressed in specific tissues; these lack TM and intracellular domains (reviewed in Boraschi and Tagliabue, 2013).

IL-1R3b

An alternate transcript of IL-1R3, termed IL-1R3b, produces a variant of IL-1R3 that is 687 amino acid longer at its C-terminal domain (Lu *et al.*, 2008). IL-1R3b is exclusively expressed in the central nervous system (Smith *et al.*, 2009), in particular neurons, but absent in astrocytes (Huang *et al.*, 2011; Nguyen *et al.*, 2011; Smith *et al.*, 2009). Gene deficiency of IL-1R3b appears to confer a local neuroprotective role during cerebral inflammation, but no role in peripheral responses, as opposed to IL-1R3 (Gosselin *et al.*, 2013; Smith *et al.*, 2009). These findings seem to suggest that the same receptor may be used in different tissues or organelles to achieve specific functions that may further highlight the pleiotropic effects of IL-1 family members.

Therapeutic Targeting of IL-1R

Clinical treatment of patients suffering IL-1 driven disease cryopyrin-associated periodic syndrome (CAPS) with IL-1R directed therapies has highlighted the potential of targeting the IL-1R complex (Dinarello *et al.*, 2012). A recombinant form of IL-1 α called Anakinra, approved in 2001, has proved effective in treating a broad range of diseases such as autoimmune hearing loss, hidradenitis suppurativa, stroke, and arthritis. Canakinumab is a human monoclonal antibody that targets IL-1 β , disrupting its ability to bind IL-1R1. It has been successful in the treatment of CAPS patients along with refractory gout and systemic onset juvenile idiopathic arthritis. Canakinumab is in several clinical trials currently, including the CANTOS study (clinical trial number NCT01327846), to examine if reducing IL-1R activation decreases rates of recurrent myocardial infarction, stroke, and cardiovascular death among stable patients with coronary artery disease.

IL-10/IL-22 Receptors

The nine known IL-10 cytokine family members (interleukins IL-10, IL-19, IL-20, IL-22, IL-24, and IL-26; and the interferon (IFN)- λ members IFN λ 1 (IL-28 α), IFN λ 2 (IL-28 β), and IFN λ 3 (IL-29)) belong to the type II cytokines, with IL-10 described as the master anti-inflammatory cytokine. IL-10 is expressed by numerous immune cells including dendritic cells, macrophages, T cells, and eosinophils; whereas IL-22 is produced by T cells, innate lymphoid cells, and epithelial cells (Rutz *et al.*, 2013; Sabat, 2010; Sabat *et al.*, 2014; Striz *et al.*, 2014; Tsai *et al.*, 2013). Apart from IL-22, the IL-10 cytokine family directly regulates the function of immune cells and maintains the balance between overexuberant and beneficial innate immunity responses. IL-22 targets cells of the pancreas, liver, kidney, and joints; as well as cells at outer-body barriers like the skin (Kong *et al.*, 2013; Mizoguchi, 2012; Pan *et al.*, 2013; Rutz *et al.*, 2013; Sabat *et al.*, 2014). Viruses such as human immunodeficiency virus, dengue virus and Epstein-Barr virus can evade immune responses by increasing host IL-10 production or by expressing their own virally encoded IL-10 homologs (Ouyang *et al.*, 2014; Slobedman *et al.*, 2009). Recent evidence suggests that IL-10 cytokines may have potential clinical relevance in stroke, cardio-protection, pancreatitis, chronic kidney disease, inflammatory bowel disease, graft-versus-host disease, cancer, wound healing and immune protection against bacterial, nematode, fungal, viral, and protozoa infections (Bodhankar *et al.*, 2013; Hamidullah *et al.*, 2012; King *et al.*, 2014; Kong *et al.*, 2013; Leung and Loke, 2013; Mizoguchi, 2012; Pan *et al.*, 2013; Rutz *et al.*, 2013; Sabat, 2010; Sabat *et al.*, 2014; Wang *et al.*, 2013; Zdanov, 2010).

The IL-10 cytokines consist of five to seven α -helices with the signature left-handed four-helix bundle typical of helical cytokines (Figures 1 and 2); their pairwise sequence identity ranges from 9% to 40% (Bleicher *et al.*, 2008; de Moura *et al.*, 2009; Jones *et al.*, 2008; Josephson *et al.*, 2001; Nagem *et al.*, 2002; Sabat, 2010; Yoon *et al.*, 2010). IL-10 exists as a domain-swapped dimer; IL-19, IL-20, IL-22, IL-24, IFN λ 1, IFN λ 2, and IFN λ 3 are functional monomers and IL-26 is active either as a dimer or monomer (Josephson *et al.*, 2001; Nagem *et al.*, 2002; Zdanov, 2010). Generally the cytokine first binds with high affinity to one receptor (for IL-10 and IL-22 it is the IL-10R1 and IL-22R1 receptor, respectively) and then the binary complex binds with lower affinity to a second common receptor, IL-10R2, leading to JAK1/TYK2/STAT3 activation (Jones *et al.*, 2008; Logsdon *et al.*, 2004; Sabat *et al.*, 2014; Yoon *et al.*, 2006; Zdanov, 2010).

Although no ternary receptor complexes have yet been determined, the binary complexes of IL-10:IL-10R1, IL-22:IL-22R1 and IL-22:IL-22BP are structurally very similar to each other and the isolated IL-10R2 structure is also available (Figure 2; Bleicher *et al.*, 2008; de Moura *et al.*, 2009; Jones *et al.*, 2008; Josephson *et al.*, 2001; Yoon *et al.*, 2006, 2010). The receptors have the same domain architecture as hGHR, with two FnIII domains, and the cytokine interacts in a similar fashion to hGH (Figure 1). IL-10R1 and IL-22R1 share 22% sequence identity. IL-22 binding protein (IL-22BP) is a naturally occurring soluble receptor containing only an extracellular region and it shares ~30% sequence identity with the

extracellular regions of both IL-22R1 and IL-10R2 (de Moura *et al.*, 2009). Homology models of the IL-10:IL-10R1:IL-10R2 and IL-22:IL-22R1:IL-10R2 ternary complexes (Bleicher *et al.*, 2008; Pletnev *et al.*, 2005; Yoon *et al.*, 2010), together with surface plasmon resonance measurements (Logsdon *et al.*, 2004; Yoon *et al.*, 2006, 2010) and alanine scanning mutagenesis studies (Logsdon *et al.*, 2004), suggest that IL-10R1/22R1 and IL-10R2 interact via their membrane-proximal D2 domains (Figure 1, Site 3) and that IL-10/22 interacts with both receptor chains through distinct binding sites (Figure 1, Sites 1 and 2).

IL-17 Receptors

There are six members in the pro-inflammatory IL-17 family of cytokines, designated IL-17A through to IL-17F (Figure 2), and they are important regulators of both innate and adaptive immune responses (Baeten and Kuchroo, 2013; Ely *et al.*, 2009; Kirkham *et al.*, 2013; Striz *et al.*, 2014; Zhang *et al.*, 2013). IL-17 cytokines are produced by numerous cell types including TH17 helper T cells, macrophages, dendritic cells, NK cells, innate lymphoid cells and epithelial cells (Baeten and Kuchroo, 2013; Kirkham *et al.*, 2013; Striz *et al.*, 2014; Zhang *et al.*, 2013). These cytokines are involved in host defense against bacteria and fungi and dysregulation of their production may contribute to inflammatory and autoimmune disorders such as multiple sclerosis, rheumatoid arthritis, psoriasis, uveitis, and ankylosing spondylitis (Baeten and Kuchroo, 2013; Blalock *et al.*, 2013; Kirkham *et al.*, 2013; Korn *et al.*, 2009; Striz *et al.*, 2014). The crystal structures of IL-17A and IL-17F reveal that they adopt a typical cysteine knot fold and assemble as disulfide-linked homodimers, in addition IL-17A and IL-17F form functional heterodimers (Ely *et al.*, 2009; Hymowitz *et al.*, 2001; Kirkham *et al.*, 2013; Liu *et al.*, 2013). Each IL-17A/F monomer is composed of two pairs of anti-parallel β -sheets. The other IL-17 cytokines have varying homology with IL-17A ranging from 16% to 50% (Kirkham *et al.*, 2013).

The five IL-17 receptor subtypes, IL-17RA through to IL-17RE, are single TM proteins with their extracellular region containing two atypical FnIII domains and their cytoplasmic tail containing a unique receptor signaling motif known as the 'similar expression to fibroblast-growth factor genes and IL-17R' (SEFIR) domain (Ely *et al.*, 2009; Gu *et al.*, 2013; Liu *et al.*, 2013; Zhang *et al.*, 2013). IL-17 receptor signaling requires the NF κ B activator 1 (Act1), which also contains a SEFIR domain. Upon cytokine stimulation Act1 is recruited to IL-17R complexes in a SEFIR-dependent manner (Ely *et al.*, 2009; Kirkham *et al.*, 2013; Zhang *et al.*, 2013). The crystal structure of the isolated IL-17RB SEFIR domain consists of six α -helices wrapped around a five-stranded parallel β -sheet core (Zhang *et al.*, 2013).

In the IL-17A dimer:IL-17RA and IL-17F dimer:IL-17RA complexes the two FnIII domains of IL-17RA (Figure 2) are arranged in a linear fashion, rather than set at right angles to each other as observed in the classical receptors (Figure 1), and the manner in which the cytokine interacts is quite distinct from other cytokine receptor systems (Ely *et al.*, 2009; Liu *et al.*, 2013). The cytokine binds edge on to the two FnIII

domains of IL-17RA in a groove between the IL-17 dimer interface, burying $\sim 2200 \text{ \AA}^2$ of the receptor surface area. The majority of the interaction ($\sim 70\%$) involves the membrane-distal D1 FnIII domain of IL-17RA. The cytokine undergoes conformational changes in peripheral strands and loops to facilitate receptor binding (Ely *et al.*, 2009; Hymowitz *et al.*, 2001; Liu *et al.*, 2013). IL-17RA appears to act as a common receptor for the IL-17 cytokine family analogous to those in type I cytokine receptor complexes (Ely *et al.*, 2009; Liu *et al.*, 2013). IL-17A, IL-17F homodimers and the heterodimeric IL-17A/IL-17F require both IL-17RA and IL-17RC for signaling (Gu *et al.*, 2013; Kirkham *et al.*, 2013; Wright *et al.*, 2008). IL-17RA and IL-17RE are thought to interact with IL-17C, while IL-17RA and IL-17RB interact with IL-17E (also known as IL-25) (Gu *et al.*, 2013; Kirkham *et al.*, 2013). Binding to the first receptor with high affinity (low nM) modulates the affinity and specificity of the second receptor binding event (typically $\sim 150\text{--}300 \text{ nM}$), promoting heterodimeric rather than homodimeric complex formation (Ely *et al.*, 2009; Hymowitz *et al.*, 2001; Liu *et al.*, 2013).

IFN Receptors

The IFNs are broadly distinguished from other cytokines by their ability to directly interfere with viral replication (Isaacs and Lindenmann, 1957). Interferons are classified into three types based on their amino acid sequence, cognate receptor system and to a lesser extent producing cell and stimulus. Type I IFNs (incl. α , β and ϵ) signal through IFN alpha receptor (IFNAR)-1 and IFNAR2, Type II IFN (γ) signals through IFN gamma receptor (IFNGR)-1 and IFNGR2; Type III IFNs (λ) signal through IFN lambda receptor (IFNLR)-1 and IL10R2 (de Weerd *et al.*, 2007). (Unfortunately, the 'Type' nomenclature used to distinguish interferons can lead to confusion when discussing type I/II cytokine receptor families. In this article we distinguish the two by using all lower case for the latter). All identified IFN receptors are type II helical cytokine receptors, thereby possessing certain structural traits (Langer *et al.*, 2004) in common with their type I counterparts, such as tandem FnIII domains in the extracellular domain, conserved patterns of disulfide bonding cysteines and a single TM region (Bazan, 1990a).

Type I IFN Receptors

The Type I IFNs are a large family of proteins consisting of ~ 20 different subtypes that engage a shared receptor complex (Figure 2), comprised of high affinity (IFNAR2) and low affinity (IFNAR1) receptor components to activate JAK/STAT, CRKL, MAPK and PI3K signaling pathways. While IFNAR2-extracellular domain (ECD) is comprised of tandem FnIII domains, typical of all other known type II cytokine receptors, IFNAR1-ECD possesses four domains (D1 through to D4) in the extracellular region. Structures for IFNAR2-ECD have been resolved by both NMR (in liganded and unliganded states) (Chill *et al.*, 2002) and crystallography (liganded state) (Thomas *et al.*, 2011), predictably revealing a receptor reminiscent of other type II cytokine receptors. Although the

structure for unliganded, full-length IFNAR1-ECD has not been determined, a structure for the three membrane-distal subdomains (D1-D3) of IFNAR1-ECD has been resolved, showing a relatively planar arrangement for these domains (Thomas *et al.*, 2011). This planar architecture appears to be maintained upon ligand binding since the crystal structure of the mIFN β :IFNAR1-ECD binary complex revealed a similar planar arrangement for the three membrane-distal subdomains of the receptor (de Weerd *et al.*, 2013). However, this structure revealed for the first time the location and presentation of the membrane-proximal subdomain (D4) of IFNAR1-ECD showing it to be transplanted away from the plane of the three membrane-distal domains (D1-D3) giving the receptor a squat appearance (de Weerd *et al.*, 2013). While NMR of IFNAR2-ECD revealed a rigid structure with only limited backbone conformational changes upon ligand engagement (Chill *et al.*, 2002), ligand binding to IFNAR1 induces a conformational change that must be propagated through the membrane-proximal D4 subdomain in order to induce signal transduction (Strunk *et al.*, 2008). The structures of the IFN α 2 variant and IFN ω ternary complexes that were recently elucidated confirmed the location of the IFNAR1 and IFNAR2 binding sites on opposing faces of the IFNs, and revealed considerable conservation in the modes of docking of the two IFN subtypes and residues involved in the interfaces with IFNAR2-ECD (Thomas *et al.*, 2011).

Type II IFN Receptors

IFN γ is the lone Type II IFN, and signals through high affinity (IFNGR1) and low affinity (IFNGR2) receptors (de Weerd and Nguyen, 2012). The structure of the functional IFN γ dimer in complex with its high affinity receptor IFNGR1 has been determined revealing that the cytokine homodimer binds to two molecules of the high affinity IFNGR1 on identical related surfaces of the cytokine homodimer (Walter *et al.*, 1995). The interaction between IFN γ and IFNGR1 resembles other type II cytokine receptor interactions, including those of tissue factor (Banner *et al.*, 1996) and IL-10R1 (Josephson *et al.*, 2001) with their ligands, but differs from those of the type I cytokine receptors in the relative presentation of the subdomains and the orientation of ligands (Walter *et al.*, 1995). Crystal structures for the low affinity receptor, IFNGR2 and the ternary IFN γ :IFNGR1:IFNGR2 complex have not yet been determined.

Type III IFN Receptors

Initially termed IL-28/29 (Sheppard *et al.*, 2003), the Type III IFNs (IFN λ 1–3) function as monomeric cytokines engaging a unique high affinity receptor, IFNLR1, and also utilizing the IL-10R2 chain as their low affinity receptor as discussed above (Kotenko *et al.*, 2003). Activities of the Type III IFNs are limited to epithelial cells and some dendritic cells due to the restricted cell surface expression of the IFNLR1 receptor (de Weerd and Nguyen, 2012). The crystal structure of IFN λ 3 demonstrated the topological similarity between the Type III IFNs and IL-10 family cytokines, in particular IL-22 (Gad *et al.*, 2009); it is therefore not surprising that the Type III IFNs signal via the IL-10R2 receptor (Langer *et al.*, 2004). The crystal

structure of ligand-bound IFNLR1 further revealed the structural similarities between this receptor and IL-10R1 and IL-10R2 (Miknis *et al.*, 2010). However, the manner in which the ligand docks onto its high affinity receptor is distinct from that of the IL-10:IL-10R1 interaction, with IFN λ 1 and IL-10 binding at different angles around the elbow between the two FnIII domains of their respective receptors (Miknis *et al.*, 2010).

Intracellular Signaling Complexes

The binding of a cytokine to the extracellular domain of its cognate receptor triggers signaling events within the receptor cytoplasmic domain that ultimately lead to the regulation of specific cellular outcomes. The ability of receptor cytoplasmic tails to function as scaffolds upon which signaling complexes are assembled allows the activated receptor to physically couple to downstream pathways. In particular, phosphorylation of the cytoplasmic tails of receptors in response to cytokine allows the recruitment and binding of a diverse array of signaling proteins that include enzymes (e.g., kinases, phosphatases, GTPases, and ubiquitin ligases), adapter proteins, and transcription factors.

Type I and type II cytokine receptors lack intrinsic tyrosine kinase activity but are able to activate the JAKs which consist of four members (JAK1, JAK2, JAK3, and TYK2) and which constitutively associate with weakly conserved 'box 1' and 'box 2' motifs in the membrane-proximal regions of receptors (Kiu and Nicholson, 2012; Wilks, 1989). High-affinity ligand binding induces either receptor oligomerization (e.g., β c family of receptors, gp130 family of receptors) and/or conformational changes (e.g. EPOR, hGHR), which serve to juxtapose the receptor cytoplasmic domains and their associated JAKs leading to transphosphorylation of receptor cytoplasmic tails. The tyrosine phosphorylation of receptor cytoplasmic tails provides docking sites for the binding of proteins containing Src Homology-2 (SH2)- or phosphotyrosine binding (PTB)-domains (Pawson, 2004). Further tyrosine phosphorylation of recruited proteins then allows the formation of higher order complexes on the receptor cytoplasmic tail mediated by a network of SH2 and PTB interactions. For example, JAKs have been shown to phosphorylate the STAT proteins, which consist of a family of seven latent transcription factors (Kiu and Nicholson, 2012). The JAK/STAT pathway, initially identified as being activated by IFN receptors (Darnell *et al.*, 1994), has been shown to be a critical regulator of type I and type II cytokine receptor activities. For example, both the single chain cytokine receptors (EPOR, hGHR, PRLR, Figure 2), and the β c family of receptors (IL-3, GM-CSF, IL-5, Figure 2) utilize JAK2 that signal via STAT3 and STAT5 (Guthridge *et al.*, 1998; Hennighausen and Robinson, 2008). The IL-2/IL-4 receptor family activates JAK1 and JAK3 that signal via STAT1, STAT3, STAT5, and STAT6 (Imada and Leonard, 2000; Kiu and Nicholson, 2012). The gp130 cytokine receptor family activates JAK1 to signal via STAT1, STAT3, and STAT5 (Kiu and Nicholson, 2012). Furthermore, Type I and Type II IFN receptors utilize JAK1, JAK2, and TYK2 that signal via STAT1, STAT2, STAT5, and STAT6 (Darnell *et al.*, 1994; Kiu and Nicholson, 2012).

In many cases, selective recognition of phosphotyrosine motifs by different SH2- and PTB-domain proteins allows the

recruitment of unique combinations of signaling proteins to the cytoplasmic tails of different cytokine receptors providing at least one mechanism by which specific signals can be generated (Pawson, 2004). For example, a specific SH2 docking site for SH2-containing protein tyrosine phosphatase 2 (SHP2) has been demonstrated in gp130 while a specific PTB binding site for Shc has been identified in the IL-3 receptor, each of which is important for activating Ras/ERK signaling (Jenkins *et al.*, 2005; Okuda *et al.*, 1997). In contrast, the ability to recruit negative regulators is also important for ensuring the termination of cytokine signaling. For example, the recruitment of the suppressor of cytokine signaling (SOCS) proteins, consisting of eight family members, provides an important negative feedback mechanism for down-regulating cytokine signaling via several mechanisms which include JAK inhibition and the proteasomal degradation of SOCS binding partners (Yoshimura *et al.*, 2007).

In addition to tyrosine phosphorylation, cytokine receptors are also phosphorylated on serine residues, which play important roles in initiating downstream signaling events. In an analogous manner to the binding of PTB-domains to phosphotyrosine residues, signaling complexes can also be assembled by the binding of phosphoserine binding proteins/domains to phosphoserine residues in the cytoplasmic tails of cytokine receptors. For example, the 14-3-3 family of phosphoserine/threonine binding proteins are able to interact with a number of cytokine receptors including the IL-9, PRL, GM-CSF and IL-3 receptors allowing the recruitment of signaling proteins such as PI3-kinase (Guthridge *et al.*, 2000; Olayioye *et al.*, 2003; Sliva *et al.*, 2000). Furthermore, the tyrosine phosphorylation of phosphoserine/threonine binding proteins such as 14-3-3 as well as the serine phosphorylation of SH2- and PTB-domain proteins such as insulin receptor substrate-1 (IRS-1) and STATs not only provide mechanisms for the integration of both phosphotyrosine and phosphoserine pathways but also for mediating specificity in signaling downstream of pleiotropic cytokine receptors (Barry *et al.*, 2009; Guthridge *et al.*, 2000; Pesu *et al.*, 2000; Weigert *et al.*, 2006).

Concluding Remarks

Cytokine receptors are capable of mediating an extraordinary array of biological responses. Yet, following the cloning and sequencing of many cytokine receptors in the late 1980s and into the 1990s, it became evident that, despite the functional pleiotropy of type I and type II cytokine receptors, there was strong evolutionary conservation in terms of their domain organization and, to some extent, specific sequence motifs. It was not until the application of X-ray crystallography, first to cytokines, then to receptors and more recently to ligand-bound receptors that the structure–function relationships of cytokine receptors could be understood at the molecular level. This increasing knowledge in cytokine structural biology is driving new opportunities for developing novel therapies to modulate cytokine function in a diverse range of diseases including malignancies, chronic inflammation and immunological pathologies. Whilst approaches to interfere with cytokine receptor activation are currently largely based on antibodies to the cytokines themselves or to their surface receptors (Broughton

et al., 2014; Sun *et al.*, 1996) new strategies are emerging. For example, following the successes in the structure-guided rational design of therapeutics that function as antagonists of cytoplasmic protein–protein interactions (Oltsdorf *et al.*, 2005), similar approaches are now being applied to identify compounds that antagonize cytokine–receptor interactions. In contrast, our understanding of the molecular structure of cytokine receptor cytoplasmic tails has lagged considerably (Brooks *et al.*, 2014). Although cytokine receptor cytoplasmic tails are widely depicted as disordered linear sequences, this is unlikely to be the case given the frequency with which disease-related mutations in cytoplasmic domains (particularly proline substitutions which disrupt secondary structure) lie outside known phosphotyrosine and phosphoserine docking sites. Thus, an important future challenge will be to understand the structure–function relationships for cytokine receptor cytoplasmic domains and apply that understanding to the development of new therapies for the treatment of human diseases.

TGF- β Superfamily Signaling

DSJ Miller and CS Hill, Cancer Research UK London Research Institute, London, UK

Introduction

The transforming growth factor β (TGF- β) superfamily of secreted ligands are found in all metazoans and emerged with multicellularity. They were originally thought to have evolved with dorsal-ventral (DV) patterning and thus only to be found in bilateria. However, it is now clear that TGF- β superfamily ligands are also found in sponges (Porifera) and in *Trichoplax adhaerens* (Placozoa) (Adamska *et al.*, 2007; Huminiecki *et al.*, 2009), indicating the ancient origin of these ligands. In humans the TGF- β superfamily comprises the TGF- β s themselves, activins, NODAL, bone morphogenetic proteins

(BMPs), growth and differentiation factors (GDFs), anti-Müllerian hormone (AMH) and also the two LEFTY proteins and INHA that act as ligand antagonists (Figure 1). In this article we will begin by outlining some of the key functions for which the TGF- β superfamily members are required. We will go on to describe how the ligands are produced and regulated, their cell surface receptors and how they signal to the nucleus through the intracellular transducers, the SMADs. After a general discussion about pathway regulation, we will end by highlighting a number of human diseases that are caused by mutation or loss of key components of TGF- β superfamily pathways.

Figure 1 Components of TGF- β superfamily signaling. (a) Phylogenetic tree of all mammalian TGF- β superfamily ligands. (b) Phylogenetic tree of ligand antagonists. Antagonists are often described in the literature by their alternative names: TWSG1, twisted gastrulation 1; FST, follistatin; FSTL3, follistatin-like 3; CHRDL1, chordin-like 1; CHRDL, chordin; SOSTDC1, USAG1; SOST, sclerostin; NOG, noggin; NBL1, DAN; GREM2, PRDC; GREM1, gremlin 1; CER1, cerberus 1; DAND5, COCO. (c) Phylogenetic tree of TGF- β superfamily receptors. Type I and type II receptors are indicated. (d) Phylogenetic tree of SMAD transcription factors. R-SMADs, co-SMAD and I-SMADs are indicated. Note that SMAD9 was originally named SMAD8. For more details about the TGF- β superfamily components please see entries in the GeneCards website <http://www.genecards.org/> and, in the case of the SMADs, also the following website <http://smad.maciasnmr.net/>.

Function of TGF- β Superfamily Signaling

The TGF- β superfamily ligands primarily function in a paracrine fashion. They bind and activate cell surface receptors on neighboring cells, which signal to the nucleus to induce new programs of gene expression. Signaling by these ligands can

regulate many different cellular behaviors, among which are cell proliferation, differentiation, migration, invasion, adhesion, and apoptosis (Massague, 2012). As a result of their ability to regulate such a diversity of cellular activities, they play critical functional roles in many aspects of early embryonic development and tissue homeostasis in adults (Figure 2).

Figure 2 Perturbation of multiple components of TGF- β superfamily signaling lead to developmental defects in a wide range of organisms.

Developmental Biology 296, 298–314.

(f) A planarian with RNAi directed against the BMP2/4/DPP-like gene *smedbmp4-1* fails in lateral regeneration after amputation, while those treated with the control RNAi regenerated normally. Reproduced with permission from Reddien, P.W., Bermange, A.L., Kicza, A.M., Sanchez Alvarado, A., 2007. BMP signaling regulates the dorsal planarian midline and is needed for asymmetric regeneration. Development 134, 4043–4051.

Their roles are too numerous to outline in detail, so we will focus on some illustrative examples.

In very early embryos, the main roles of TGF- β superfamily members are in specifying the germ layers, patterning tissues across the different axes and maintaining pluripotency. For example, in zebrafish and *Xenopus*, graded BMP signaling determines the DV axis and is responsible for specifying and patterning tissues across this axis (Ramel and Hill, 2012). This role in DV patterning is also evident in arthropods such as *Drosophila*, although the DV axis is inverted in this case (De Robertis and Kuroda, 2004). The earliest role of NODAL in the mouse embryo is in the maintenance of the determinants of pluripotency, such as POU5F1 (Oct4) and NANOG at the blastocyst stage (Mesnard *et al.*, 2006). After implantation, graded NODAL signaling is important for defining the proximal–distal axis, which establishes the anterior–posterior axis of the embryo (Arnold and Robertson, 2009). NODAL signaling also functions in conjunction with WNT and BMP signaling to induce mesoderm and endoderm. At later stages, NODAL is required for left–right axis formation and patterning. The role for NODAL in mesendoderm differentiation and patterning and left–right asymmetry is also evident in zebrafish (Figure 2(d)), *Xenopus* and sea urchins (Duboc *et al.*, 2010; Schier, 2003). In many of these contexts, graded NODAL signaling is antagonized by a reverse gradient of BMP signaling, and in fact opposing gradients of BMP and NODAL signaling are sufficient to organize uncommitted cells of the zebrafish blastula animal pole into an embryo (Xu *et al.*, 2014). Later in development, BMPs and GDFs play critical roles in organogenesis, including development of bone and cartilage, heart, lung, kidney, eyes, reproductive systems, nervous system, placenta and placental connections, vasculogenesis, and angiogenesis (Miyazono *et al.*, 2010). Postnatally, BMPs play important roles in the induction of bone and cartilage formation, vascular homeostasis, and in iron metabolism (Corradini *et al.*, 2009).

The major developmental roles of the TGF- β s, as revealed by the phenotypes of mice deleted for TGF- β 1, 2 and 3, are in vasculogenesis, haematopoiesis, and development of a variety of organs (Goumans and Mummery, 2000). In adults, TGF- β s are important for controlling immunity, inflammation, wound healing and bone, muscle, adipose, vascular, and haematopoietic homeostasis (Massague, 2012). Activins were originally identified by virtue of their ability to stimulate release of follicle stimulating hormone from the pituitary and, in addition, control hormone production in the gonads and placenta, and regulate gametogenesis (Antsiferova and Werner, 2012). AMH plays a much more restricted role than many other TGF- β family members, being responsible for inducing regression of the Müllerian ducts during male sex differentiation, and it has an important role in ovarian folliculogenesis in females (Durlinger *et al.*, 2002).

TGF- β Superfamily Ligands

The TGF- β superfamily ligands function as disulphide-linked dimers, and the mature domain of the ligands forms a cystine knot, that is stabilized by three intramolecular disulphide bonds between six strictly conserved cysteine residues.

They are thus members of the so-called cystine knot family that also contains other hormones and growth factors such as nerve growth factor, platelet-derived growth factor and human chorionic gonadotrophin (Murray-Rust *et al.*, 1993). All the TGF- β superfamily ligands except GDF3, GDF9, and BMP15 use an additional conserved cysteine to form an inter-molecular disulphide bond that stabilizes the dimer. Although most ligands appear to act as homodimers, ligand heterodimerization has also been demonstrated. Prominent examples are activin β A– β B heterodimers (Antsiferova and Werner, 2012), and heterodimers formed between BMP15 and GDF9 (Peng *et al.*, 2013) and between NODAL and GDF1 (Tanaka *et al.*, 2007). Furthermore, in zebrafish, BMP2 and BMP7 form obligate heterodimers which are required for signaling in the early embryo (Little and Mullins, 2009).

TGF- β superfamily ligands are all synthesized as precursors, with a large prodomain and a C-terminal mature domain. Dimerization is thought to occur intracellularly and depends on the presence of the prodomain (Gray and Mason, 1990). Cleavage of the mature domain from the prodomain is subsequently mediated by proteases of the subtilisin-like proprotein convertase (SPC) family (Constam and Robertson, 1999, 2000). Some of the ligands have multiple cleavage sites and recent data suggest that for BMP4 these cleavages must be sequential rather than simultaneous in order to preserve ligand function (Tilak *et al.*, 2014). The TGF- β s themselves, as well as GDF8 and the closely related GDF11, are secreted as latent forms still non-covalently attached to their propeptides (Ge *et al.*, 2005; Shi *et al.*, 2011). In the case of the TGF- β s the latent ligand forms a disulphide-linked complex with LTBP (latent TGF- β binding proteins) (Annes *et al.*, 2003), which associate with the extracellular matrix through interactions with fibrillins (Ramirez and Sakai, 2010). This regulates diffusion, storage, presentation, and release of the active TGF- β s. A further activation step is required to release the active ligand (Box 1). In the case of TGF- β 1 and TGF- β 3, this involves the binding of $\alpha_v\beta_6$ or $\alpha_v\beta_8$ integrins to RGD motifs in the prodomains of the ligands (Shi *et al.*, 2011), but other mechanisms involving proteases, thrombospondin 1, reactive oxygen species and low pH, can also activate TGF- β (Annes *et al.*, 2003). In the case of GDF11, ligand activation requires metalloproteinases of the BMP1/tolloid family (Ge *et al.*, 2005).

TGF- β Receptors

TGF- β superfamily ligands signal through two types of serine/threonine kinase receptors, a type I (TGFBR1, ACVRL1, ACVR1, ACVR1B, ACVR1C, BMPR1A, or BMPR1B) and a type II (ACVR2A, ACVR2B, TGFBR2, BMPR2, or AMHR2) (Shi and Massague, 2003; Table 1; Figure 1). Type II receptors consist of an extracellular ligand-binding domain, a membrane-spanning region and an internal, constitutively active, kinase domain. Type I receptors are closely related to the type II receptors and have a similar structural organization (Figure 1). They additionally contain a highly conserved intracellular glycine- and serine-rich (GS) domain, close to the membrane-spanning region. Receptors signal through a conserved mechanism. Ligand binding permits the type II receptor to

Box 1 Release of mature TGF- β from the latency complex

Mature TGF- β is released from the latency complex after the exertion of force through the binding of integrins. The mature TGF- β dimer is anchored in place by the 'straitjacket' region formed by a dimer of its prodomains, with the 'latency lasso' preventing the binding of ligand to the receptors and thus keeping ligand inactive. The prodomains themselves are held together in the arm region by 4 disulphide bonds forming a bowtie motif. The prodomains attach to $\alpha_v\beta_6$ or $\alpha_v\beta_8$ integrins at an RGD site in the arm region. Latent TGF- β interacts with the extracellular matrix by forming a disulphide-linked complex with LTBP, which itself interacts with fibrillins. The binding of integrins exerts a force on the complex that unfastens the straitjacket and releases mature ligand. Shown below is a linearized representation of the two full-length TGF- β monomers, indicating their structural organization. The elements are color-coded, to indicate which monomer is associated with which prodomain (Shi, M., Zhu, J., Wang, R., *et al.*, 2011. Latent TGF- β structure and activation. *Nature* 474, 343–349).

phosphorylate the type I receptor at multiple serines and threonines in its GS domain. This phosphorylation drives conformational changes that activate the type I receptor kinase and provide a binding site for its downstream substrates, the receptor-regulated SMADs (R-SMADs, see below) (Figure 1), which it phosphorylates and activates (Figure 3). Traditionally, the pathway has been divided into two main branches, with the activins, TGF- β s and NODAL leading to the phosphorylation of SMAD2 and 3, and the BMPs and GDFs leading to the phosphorylation of SMAD1, 5 and 9 (Shi and Massague, 2003). Although each type I receptor appears to activate certain SMADs preferentially, there is also evidence for the formation of mixed receptor complexes that result in a single ligand being able to activate both classes of R-SMAD (Daly *et al.*, 2008; Goumans *et al.*, 2002; Holtzhausen *et al.*, 2014).

For the canonical TGF- β superfamily ligands, activated receptor complexes consist of two type I and two type II receptors (Ehrlich *et al.*, 2012), which signal as a heterotetrameric complex (Huang *et al.*, 2011; Weis-Garcia and Massague, 1996). Although it was initially believed that complex formation was sequential, with ligand binding to the type II receptor bringing the type I receptor into the complex (Wrana *et al.*, 1994), it has also been suggested that complexes are preformed on the plasma membrane to some extent (Rechtman *et al.*, 2009; Wells *et al.*, 1999). In the case of the

TGF- β s themselves, the ligand must first bind the type II receptors to bring the type I receptors into the complex. In contrast, the BMPs show little preference for one receptor type over the other, suggesting a less sequential mechanism for receptor complex formation (Groppe *et al.*, 2008). In the inactive state, FKBP1A (FKBP12) is bound at the GS domain of type I receptors and inhibits signaling, with phosphorylation of the type I receptor releasing FKBP1A and relieving this inhibition (Wang and Donahoe, 2004).

The trafficking of receptors has been demonstrated to be critical for pathway regulation. Receptors are constitutively internalized by endocytosis in the absence and presence of ligand and can signal from endosomes (Di Guglielmo *et al.*, 2003). They have been described to either internalize uniquely into clathrin-coated pits (Mitchell *et al.*, 2004) or to additionally internalize into caveolae (Di Guglielmo *et al.*, 2003), but conflicting evidence exists over whether internalization is necessary for signaling, with different cell lines, ligands and methods for blocking internalization leading to varying conclusions (Di Guglielmo *et al.*, 2003; Hagemann *et al.*, 2009; Jullien and Gurdon, 2005; Lu *et al.*, 2002; Figure 4). ZFYVE9 (also known as Smad anchor for receptor activation (SARA)) has been proposed to associate with endosomes and to bring Smads into contact with activated receptors, which could enhance the ability of internalized receptors to signal

Table 1 Ligand–receptor–SMAD usage in TGF- β superfamily signaling

Ligand ^a	Type I receptor	Type II receptor	Co-receptors	Smads ^d

^aThe order of the ligands in the Table is the same as in the phylogenetic tree in Figure 1. Shown are the best understood cognate receptors for each ligand, their requirement for co-receptor and the SMADs that have traditionally been thought to be activated by each receptor type. In some cases, alternative SMAD complexes can also form, such as the mixed SMAD complexes that can form in response to TGF- β 1 and 3 (SMAD1/5–SMAD3) and the recently demonstrated SMAD2/3 activation by BMP2 and 4. Figure 3 Schematic representation of the generic TGF- β /SMAD pathway. Binding of ligand dimers leads to the phosphorylation of type I receptors by type II receptors and formation of a heterotetrameric receptor complex. This allows the type I receptor to phosphorylate R-SMAD transcription factors, which form complexes with SMAD4 and accumulate in the nucleus, where they regulate gene transcription with transcriptional cofactors. The action of the receptor kinase is opposed by a putative nuclear phosphatase. Ligand activity is also regulated by binding of ligand antagonists.

(Di Guglielmo *et al.*, 2003; Tsukazaki *et al.*, 1998). ZFYVE16 (endofin), a ZFYVE9 homolog, has been suggested to play an analogous role in BMP signaling (Chen *et al.*, 2007). Once internalized, receptors are either targeted for degradation in the proteasome or lysosome or are recycled back to the plasma membrane in a RAB11 dependent manner (Mitchell *et al.*, 2004; Figure 4). Resolving the exact trafficking routes of receptors has proved difficult due to a lack of reagents to localize endogenous receptors. To date, there are no antibodies that can reliably be used for immunofluorescence studies of any TGF- β superfamily receptor and it is not certain that over-expression systems fully recapitulate the behavior of the endogenous signaling pathway.

TGF- β superfamily receptors can be posttranslationally modified to regulate their localization and activity. These modifications can modulate receptor trafficking, endocytosis, recycling and degradation, and thus determine the

duration of the phospho-SMAD response. Both receptor types are glycosylated during trafficking to the membrane, which may regulate their subsequent turnover (Kim *et al.*, 2012; Wells *et al.*, 1997). In addition, ubiquitination of receptors plays a key role in regulating their stability and abundance (Figure 4). The canonical TGF- β type I receptor TGFBR1 is degraded following ubiquitination by an E3 ubiquitin ligase. Several E3 ligases have been proposed to be involved in this process, including SMURF1 (Kavak *et al.*, 2000), SMURF2 (Ogunjimi *et al.*, 2005), WWP1 (Komuro *et al.*, 2004), and NEDD4L (Kuratori *et al.*, 2005). Deubiquitinating enzymes have also been identified that reverse this process and increase receptor stability such as USP15 (Eichhorn *et al.*, 2012), UCHL5 (UCH37) (Wicks *et al.*, 2005), and USP4 (Zhang *et al.*, 2012b). Recently, TRAF4 has been identified as antagonizing the inhibitory effects of SMURF2 by recruiting USP15 to activated TGF- β type I receptors (Zhang *et al.*, 2013). In addition, TGFBR1 is sumoylated in response to TGF- β , a modification that stabilizes SMAD3 binding to the receptor and promotes signaling (Kang *et al.*, 2008). Receptor regulation is also substantially influenced by the inhibitory SMADs (I-SMADs, see below), SMAD6 and SMAD7. SMAD7 is recruited to activated receptors and can in turn recruit negative regulators of receptor signaling, including SMURF2 (Kavak *et al.*, 2000) and the GADD34-PP1c phosphatase complex (Shi *et al.*, 2004).

Several ligand–receptor interactions also require membrane-bound co-receptors for full SMAD activation. The first of these to be identified was betaglycan, which was initially considered to be a third core receptor type (hence its official name, TGFBR3). This co-receptor can enhance canonical TGF- β signaling by presenting ligand to the type II receptor (Lopez-Casillas *et al.*, 1993), and is particularly important for TGF- β 2 signaling (ten Dijke and Arthur, 2007). It can also inhibit signaling, possibly by shedding its ectodomain, releasing a soluble form of betaglycan that is capable of sequestering ligand (Elderbrook *et al.*, 2014). Shortly after the identification of betaglycan, ENG (endoglin) was isolated as a TGF- β co-receptor in endothelial cells. In these cells ENG enhances TGF- β binding to ACVRL1 and promotes phosphorylation of SMAD1/5, while inhibiting signaling through TGFBR1 and SMAD2/3, promoting cell proliferation and migration (Lebrin *et al.*, 2004).

TGF- β superfamily co-receptors also play critical roles in embryonic development. TDGF1 (also known as cripto) is an EGF-CFC (epidermal growth factor-like cripto frl-1 cryptic) protein that was first identified as having a role in TGF- β superfamily signaling when a mutant in the zebrafish homolog, one-eyed pinhead (*oep*), was shown to have the same phenotype as loss of NODAL activity (Schier, 2003). It has since been shown to act as an obligate co-receptor for NODAL/GDF1/GDF3 signaling through ACVR1B and SMAD2/3, although its mechanism of action is still in debate. It has been proposed to act either by binding ligand and presenting it to receptor complexes, by directing trafficking of ligand or activated receptors or by directing the cleavage and activation of NODAL (Constam, 2009). A second family member, CFC1 (also known as cryptic) also exists, which is important for NODAL function in left–right patterning (Schier, 2003).

Co-receptors for BMP signaling have only been identified much more recently, and fall into a single family, the repulsive

Figure 4 Receptor endocytosis following ligand stimulation. After binding ligand, receptors undergo endocytosis and continue to signal from endosomes. Signaling from endosomes may be enhanced by the presence of factors such as ZFYVE9 (SARA). Receptors could be subsequently either recycled back to the plasma membrane in RAB11-marked vesicles or poly-ubiquitinated and targeted for degradation. I-SMADs recruit inhibitory factors to activated receptors.

guidance molecule (RGM) or DRAGON family (Corradini *et al.*, 2009). These molecules may enhance signaling by allowing BMP2 and BMP4 to signal through ACVR2A in addition to BMPR2, though little is known about the precise molecular mechanism.

Co-receptors thus increase the specificity of ligand–receptor–SMAD interactions, and allow greater regulation of signaling in different cellular contexts. The co-receptors have also been shown to have important roles in the development of cancer and other diseases (ten Dijke and Arthur, 2007) (see also below).

The SMADs

SMAD transcription factors are the principal downstream effectors of TGF- β superfamily signaling. They fall into three subclasses, the receptor-regulated SMADs (R-SMADs), SMAD1, 2, 3, 5, and 9, the common mediator SMAD (co-SMAD) SMAD4, and the inhibitory SMADs (I-SMADs), SMAD6 and 7 (Figures 1 and 3; Table 1).

The R-SMADs are highly conserved across all metazoans. They contain three key structural features: an N-terminal Mad Homology 1 (MH1) domain, a C-terminal Mad Homology 2 (MH2) domain, and a less conserved proline-rich region

linking these two domains. The MH2 domain is the critical determinant of the interactions of the SMADs with other proteins, including receptors, other SMADs, co-activators and transcriptional cofactors, whereas the MH1 domain regulates nuclear import and in the case of all R-SMADs except SMAD2, can contact DNA. In addition, the MH1 domain can inhibit the activity of the MH2 domain when the SMADs are in an inactive state (Shi and Massague, 2003). Activated SMADs are phosphorylated by TGF- β superfamily type I receptors at two serine residues at an S-M/V-S motif at their extreme C-terminus. Once phosphorylated, activated R-SMADs form complexes with SMAD4, which accumulate in the nucleus where they activate or repress transcription. The exact stoichiometry of these complexes is still unclear, but they are likely to be dimeric or trimeric (with two R-SMADs and SMAD4). In addition, stimulation with TGF- β ligand can drive the formation of mixed SMAD complexes comprising phosphorylated SMAD1/5-SMAD3 that inhibit BMP responses (Gronroos *et al.*, 2012).

Pathway activation through the receptors is counteracted by the activity of nuclear phosphatases, which terminate signaling by either dissociating SMAD complexes or increasing their nuclear export rate. Several phosphatases have been identified that can dephosphorylate SMAD2/3 or SMAD1/5, including PPM1A, PP2A, MTMR4, and Pdp (Bruce and Sapkota, 2012).

It is unclear if any one of these is single-handedly responsible for terminating SMAD signaling or whether they act in combination. A proportion of activated SMADs are targeted for degradation in the proteasome. In one example of this, NEDD4L specifically recognizes TGF- β -induced phosphorylation of a threonine residue preceding a so-called PY motif in the SMAD2/3 linker, leading to SMAD polyubiquitination and degradation, thus limiting the full extent of TGF- β signaling (Gao *et al.*, 2009).

Once in the nucleus, SMADs can regulate transcription both positively and negatively. SMAD4 and all R-SMADs except SMAD2 bind DNA directly, with SMAD3 and 4 binding at SMAD binding elements (SBEs), comprising a repeated CAGAC (or its reverse complement, GTCTG) motif, while SMADs 1 and 5 bind at GC-rich GCCGNC or GRCGNC sequences (Ross and Hill, 2008). The SMADs have a low affinity for DNA, so transcriptional regulation relies heavily on the binding of co-factors that increase the specificity and affinity of SMADs for certain gene promoters and enhancers. The first of these to be identified was FOXH1, which was shown to be required for activin-mediated induction of the *Xenopus Mix.2* gene (Chen *et al.*, 1996), but has since been shown to be a general transcriptional co-activator of SMAD2 target genes during early embryonic development. Other transcriptional co-factors have subsequently been identified which can be either activatory or repressive, and cooperate with different SMADs (Ross and Hill, 2008). The requirement for these co-factors depends on both the gene under regulation and the cellular context.

SMAD binding leads to chromatin remodeling via changes in the acetylation and methylation state of histones surrounding SMAD binding sites (Ross *et al.*, 2006). The SMADs recruit histone acetyl transferases, such as p300 and CBP (Feng *et al.*, 1998) that acetylate key lysines in histone tails and promote transcriptional activation. Additionally, in response to TGF- β /activin signaling, SMAD2/3 can recruit the SWI/SNF nucleosome remodeling component SMARCA4 (BRG1) to create a favorable chromatin environment for other transcription factors to bind (Xi *et al.*, 2008). In different contexts, SMAD binding partners can also recruit histone deacetylases (HDACs) to inhibit gene expression (Kang *et al.*, 2005).

The I-SMADs, SMAD6 and 7, negatively regulate TGF- β signaling. As well as their role in recruiting negative regulators to receptors (see above), SMAD6 and 7 have been described to interfere with SMAD complex formation (Hata *et al.*, 1998; Moren *et al.*, 2005), the ability of SMADs to bind DNA and the activation of transcription by nuclear SMADs (Lin *et al.*, 2003).

SMAD activity is also regulated by several posttranslational modifications in addition to phosphorylation of the canonical S-M/V-S motif. MAP kinases (MAPKs) and cyclin-dependent kinases (CDKs) can phosphorylate R-SMADs at Ser/Thr-Pro motifs in the linker region (Massague, 2012). Linker phosphorylation has been shown to lead to the degradation of activated SMADs by recruiting E3 ubiquitin ligases which polyubiquitinate SMADs. SMAD1/5 linker phosphorylation by MAPKs and GSK3 recruits the E3 ligase SMURF1 (Sapkota *et al.*, 2007), while SMAD2/3 is ubiquitinated in an analogous fashion by NEDD4L (Gao *et al.*, 2009). The deubiquitinase USP15 was recently identified as being able to counteract these

processes and stabilize activated SMADs (Inui *et al.*, 2011). Chromatin-bound SMAD4 is regulated through mono-ubiquitination by TRIM33 (TIF1 γ), which acts to reduce the residence time of SMAD complexes on DNA (Agricola *et al.*, 2011). In addition, R-SMADs have been shown to be regulated by acetylation (Simonsson *et al.*, 2006), PARylation (Lonn *et al.*, 2010), and sumoylation (Lee *et al.*, 2003), highlighting the critical importance of controlling SMAD levels and localization within the cell.

The I-SMADs are also subject to regulation through post-translational modifications. The RING domain-containing E3 ligase RNF12 binds to SMAD7, inducing its polyubiquitination and degradation (Zhang *et al.*, 2012a). SMAD6 has been shown to be regulated by arginine methylation via the methyltransferase PRMT1 (Xu *et al.*, 2013). This methylation leads to relocalization of SMAD6 away from receptors, facilitating R-SMAD recruitment and activation.

Pathway Modulation

TGF- β signaling is subject to complex regulation, as might be expected from a pathway whose activation and inactivation at the right time and place is critical for the normal development of metazoans. Regulation occurs at all levels of the pathway, from ligands to SMADs, but the mechanisms that elicit this regulation vary in different cellular contexts and between TGF- β superfamily pathways. Although many positive and negative regulators of TGF- β signaling have been identified, common principles underlie their mechanism of action, which will be described below. These regulators do not necessarily lead to simple activation or suppression of the pathway as a whole, but instead act like a rheostat, where multiple positive and negative inputs favor more or less pathway activity and thus modulate signaling.

Ligand activity is regulated both by the release of ligand from inactive conformations and by secreted inhibitors. Gradients of ligand activity have long been understood to be involved in the patterning of embryos during development, and are often regulated by opposing gradients of antagonists. These antagonists generally function by binding and sequestering ligands, as is the case for BMP antagonists such as NOG (noggin) and CHRD (chordin) or the activin antagonist FST (follistatin) (Figure 1). One exception to this is the inhibition of NODAL signaling by LEFTY1/2. LEFTY1/2 are secreted antagonists necessary for normal mesendoderm induction and left-right patterning in vertebrates (Shiratori and Hamada, 2014). As members of the TGF- β superfamily, their sequence is similar to the ligands themselves, so they are likely to mediate ligand antagonism by a different mechanism, such as sequestration of the co-receptor TDGF1 (Chen and Shen, 2004; Cheng *et al.*, 2004). Because LEFTY1/2 are targets of NODAL signaling, they can generate a negative feedback loop in developmental contexts, where pathway activity is shut off when signaling is sustained (Schier, 2003). In addition to these negative regulators of TGF- β signaling, several ligand agonists have been identified that enhance the ability of ligand to activate receptors. One example of this is BMPER (crossveinless 2), which acts in developmental contexts to enhance BMP activity in specific spatial domains (Reichert *et al.*, 2013; Serpe *et al.*, 2008).

Figure 5 SMAD nucleocytoplasmic shuttling allows continuous monitoring of receptor activity. (a) In the absence of signal, SMADs shuttle into and out of the nucleus at a continuous rate. Monomeric R-SMADs have a higher nuclear export rate than import rate so appear predominantly located in the cytoplasm, while SMAD4 is distributed evenly between the cytoplasm and nucleus. (b) When receptors are signaling, the SMADs form complexes that have a higher nuclear import rate than the monomeric SMADs and cannot be exported until dissociated. Thus, the overall nuclear import rate exceeds the export rate and this drives SMAD accumulation in the nucleus.

Recent work has indicated that the level of activated receptors does not necessarily correlate with levels of ligand in the extracellular milieu. After acute TGF- β stimulation, receptors are rapidly depleted from the surface of cells, although signaling is sustained for several hours after this point (Vizan *et al.*, 2013). This renders the cells refractory to further acute stimulation, until the ligand is depleted and surface receptor levels recover. Sustained signaling from internalized receptors in the absence of extracellular ligand has also been observed in *Xenopus* embryos responding to activin (Jullien and Gurdon, 2005). In embryonic contexts, cells have to interpret a transient presence of ligands and translate that into a sustained response. *Xenopus* embryos appear to have a long-term cellular 'memory' for ligand, with activated receptors signaling for several hours after ligand has disappeared.

Although pathway activation is not a direct corollary of ligand levels, continuous monitoring of receptor activity does occur. The R-SMADs and SMAD4 continuously shuttle into and out of the nucleus, even in the absence of pathway activation (Inman *et al.*, 2002; Xu *et al.*, 2002). Receptor activity drives the formation of complexes, which are prevented from being exported from the nucleus, and have a higher nuclear import rate than monomeric SMADs and so accumulate in the nucleus upon ligand induction (Schmierer *et al.*, 2008; Figure 5; Movies 1 and 2). When receptors are turned off, the SMADs gradually reaccumulate in the cytoplasm. At any time, the level of activated SMAD complexes in the nucleus will be a

direct result of the relative activity of the receptor kinase and the nuclear phosphatase. This dynamic nucleocytoplasmic shuttling allows cells to continuously monitor pathway activation, with levels of nuclear SMADs directly reflecting receptor activity.

Pathway activation can lead to the initiation of both positive and negative feedback cycles in different contexts. These can act at the transcriptional level or feed back onto the core TGF- β pathway components. An example of a transcriptional feedforward loop involves the homeodomain transcription factor Mixer, which regulates the expression of key NODAL target genes in development, such as *gooseoid*, by acting as transcriptional co-factor for SMAD2-SMAD4 complexes (Germain *et al.*, 2000; Kunwar *et al.*, 2003). Mixer is itself a transcriptional target of NODAL signaling, so forms part of a positive feedback loop to upregulate developmental genes, and allows amplification of an initial NODAL signal. Another transcriptional feedback loop with a similar mechanism, but the opposite outcome, was termed the self-enabling response (Kang *et al.*, 2003). Here, activated SMAD3 directly induces the transcription of *ATF3*, which encodes a transcriptional repressor. This then enables a secondary response where SMAD3 co-operates with ATF3 to down-regulate the expression of a gene encoding a key inhibitor of differentiation, *ID1*.

Negative feedback loops can act on pathway components themselves to limit the overall level of signaling.

Negative regulators of the pathway, including the previously described I-SMADs and SMURF1/2, as well as transcriptional co-repressors such as c-SKI and SKIL (also known as SnoN) can be direct targets of TGF- β superfamily signaling. Feedback loops can also act together to generate transient responses to pathway activation. A well-understood example of this involves the E3 ubiquitin ligase RNF111 (also known as Arkadia) and SKIL (Levy *et al.*, 2007). SKIL binds with SMAD4 in the inactive state to recruit transcriptional co-repressors to DNA at SBEs. Upon pathway activation, RNF111 bound to phosphorylated SMAD2/3 can ubiquitinate and promote degradation of SKIL, allowing transcription of the target genes via activated SMAD complexes. One of these target genes is *SKIL* itself, which accumulates in response to signaling and represses further transcriptional activation by the pathway. Recently, several microRNAs (miRNAs) have been described that act to regulate TGF- β superfamily signaling in mammalian cells, by downregulating receptors (Martello *et al.*, 2007) or ligands (Choi *et al.*, 2007). The production of these miRNAs can also be regulated in response to pathway activation, so can contribute to feedback loops (Kang *et al.*, 2012).

TGF- β Superfamily Signaling and Disease

Consistent with the importance of TGF- β superfamily signaling in embryonic development and tissue homeostasis, mutation or loss of core components of the pathways results in serious human diseases that affect many different organs of the body (Figure 6). One of the earliest to be identified was Hereditary Hemorrhagic Telangiectasia (HHT), which is characterized by bleeding from small vascular lesions in the mucocutaneous tissues, and arteriovenous malformations in the lung, liver and/or cerebral vasculature (ten Dijke and Arthur, 2007). HHT results from heterozygous mutations either in the TGF- β co-receptor *ENG* that lead to haploinsufficiency, or loss-of-function or dominant negative mutations in the type I receptor *ACVRL1* (Johnson *et al.*, 1996; McAllister *et al.*, 1994). This can readily be rationalized as *ACVRL1* and *ENG*, along with *TGFBR1* and *TGFBR2* are known to transduce TGF- β responses in endothelial cells (ten Dijke and Arthur, 2007). Mutation of other key components of TGF- β superfamily pathways also affect the cardiovascular system. One of the main features of the connective tissue disorders Marfan syndrome (MFS) and Loeys-Dietz syndrome (LDS), is a strong predisposition for

Figure 6 Mutations in TGF- β superfamily signaling components underlie a diverse range of human diseases. Indicated are the diseases that are best understood to commonly be driven by mutations in TGF- β signaling components, and the main organ or system they affect. The most common components to be mutated for each condition are highlighted in red.

aortic root aneurysms, along with long bone overgrowth, spine curvature and ocular lens dislocation, among other manifestations (Doyle *et al.*, 2012b). MFS is associated with heterozygous mutations in *FBN1* (fibrillin-1), whereas the related LDS results from heterozygous missense mutations in either *TGFBR1* or *TGFBR2*. Two other syndromes with significant overlap with MFS and LDS are Shprintzen–Goldberg syndrome (Doyle *et al.*, 2012a) and Aneurysms-osteoarthritis syndrome (van de Laar *et al.*, 2012), which are caused by heterozygous mutations in *SKI* and *SMAD3* respectively. Deregulated TGF- β signaling appears to be the underlying cause of all of these syndromes, but exactly how this results in altered extracellular matrix homeostasis and subsequent disease is not fully understood (Doyle *et al.*, 2012b).

Familial pulmonary hypertension is a lung disease characterized by vascular cell hyperproliferation resulting in obliteration of small pulmonary arteries, which leads to severe pulmonary hypertension and right-sided heart failure. It is associated with heterozygous loss-of-function mutations in the BMP type II receptor gene *BMPR2* (International PPH Consortium *et al.*, 2000). This is thought to lead to reduced BMP signaling in pulmonary artery smooth muscle cells and endothelial cells, causing vascular smooth muscle cell hyperproliferation. Interestingly, many of the disease-causing mutations lead to a truncation of the long cytoplasmic tail of BMPR2 protein, which is required for proper regulation of the cytoskeleton (ten Dijke and Arthur, 2007).

Germline mutations in TGF- β superfamily signaling components can also lead to cancer predisposition. The first example of this was the finding that heterozygous mutations of *SMAD4* that cause C-terminal truncations and loss of *SMAD4* function led to juvenile polyposis syndrome (JPS), which is characterized by the appearance of multiple juvenile polyps in the gastrointestinal tract, and increased risk of adenocarcinoma (Howe *et al.*, 1998). It is likely that it is BMP signaling that is affected, as other families with JPS have germline loss-of-function mutations in the BMP type I receptor *BMPR1A*. Recently, patients with a variant of JPS called hereditary mixed polyposis syndrome (HMPS) were found to have a duplication of the regulatory regions of the *GREM1* gene which encodes a BMP antagonist. The duplication results in increased expression of *GREM1*, which would be predicted to cause reduced BMP signaling (Jaeger *et al.*, 2012). Monoallelic mutations in the TGF- β type I receptor *TGFBR1* that result in truncation of the kinase domain or mutation of the ligand binding domain lead to multiple self-healing squamous epithelioma (MSSE) which is an autosomal-dominant skin cancer condition (Goudie *et al.*, 2011). These mutations are clearly loss-of-function and are entirely distinct from the missense mutations in *TGFBR1* that lead to LDS. Very recently, activating mutations in the gene encoding *ACVR1* have been associated with diffuse intrinsic pontine glioma (DIPG), which is an incurable pediatric high grade glioma (Buczkowicz *et al.*, 2014; Taylor *et al.*, 2014; Wu *et al.*, 2014). There are also numerous examples of somatic mutations in TGF- β superfamily components that result in cancer, highlighting the tumor suppressive activity of TGF- β superfamily pathways; the most prevalent being loss-of-function mutations in *SMAD4* in a high proportion of pancreatic and colon cancers, and loss-of-function mutations in *TGFBR2* in colon cancer (Levy and Hill,

2006; Wakefield and Hill, 2013). TGF- β superfamily signaling also has potent tumor promoting effects at later stages of cancer.

Intriguingly, the somatic mutations in *ACVR1* that result in DIPG give rise to a very different disease when present in the germline. This disease is the congenital childhood developmental disorder fibrodysplasia ossificans progressiva (FOP), where fibrous tissue such as skeletal muscle is transformed to bone spontaneously or when damaged (Kaplan *et al.*, 2011). Mutation of two other components of BMP/GDF signaling cause heritable developmental disorders affecting the joints. Heterozygous missense mutations in the gene encoding the BMP antagonist *NOG* causes the autosomal-dominant disorders proximal symphalangism and multiple synostoses syndrome (Gong *et al.*, 1999). In the former, osseous union results in fusions of joints in the hands and feet. In the latter, joints of the hip and cervical spine are affected. Mutations in *GDF5* result in human hereditary chondrodysplasias, which are characterized by shortening of limbs and loss of one or more joints (Luyten, 1997).

The range of diseases caused by misregulated TGF- β superfamily signaling reflects well the pleiotropic effects of these pathways in human development and homeostasis. However, the connection between the deregulated signaling and the disease manifestation in many cases is not yet clear, and will require considerable further work. The next challenge is to use our knowledge of the misregulated pathway concerned to inform the development of specific therapeutics.

Acknowledgments

We thank all the members of the Hill lab for discussions and useful comments on the manuscript. We thank Dr Bernhard Schmierer for the movies of *SMAD* nucleocytoplasmic shuttling. Work in the Hill lab is funded by Cancer Research UK, the Wates Foundation and the European Commission Network of Excellence EpiGeneSys [HEALTH-F4-2010-257082].

G Protein-Coupled Receptors

G Protein-Coupled Receptors (GPCRs), which convey the messages borne by several ligands such as hormones, neurotransmitters, odorants, or phospholipids, are ubiquitous through the phylogenetic spectrum. GPCRs are coded by a gene family representing 5% of human genome. Activation of these receptors, in turn, regulates diverse downstream signaling pathways that are crucial for normal physiological responses. Therefore, GPCRs are the targets for about half of the drugs in current use (Morris and Malbon, 1999; Ji *et al.*, 1998; Flower, 1999). GPCRs form complexes with heterotrimeric G proteins ($G\alpha$ and $G\beta\gamma$ subunits). They are activated by an external signal (ligand) that induces a conformational change in the receptor, causing activation of a G protein. The diversity of GPCRs is determined by the variety of stimuli and their effects depend on different types of G proteins with which they couple.

We often associate GPCRs with conventional signaling pathways, the generation of intracellular second messengers such as cAMP, inositol trisphosphate, or calcium. More recently, it has become evident that these receptors also engage intracellular signaling pathways through integration of several networks. For example, MAPKs (mitogen-activated protein kinases) and JNK (c-Jun N-terminal kinases) network has been shown to link GPCRs to the nucleus where they mediate cell proliferation (Marinissen and Gutkind, 2001). In addition, several effectors for GPCR that are independent of G proteins have also been identified. β -arrestins internalize in response to GPCR activation and engage intracellular signaling cascades described in this section.

In this article we will diverge from either of these G protein signaling pathways and address the information connecting GFs and GPCR, emphasizing on cross talk between growth factor and GPCRs that results in modification of microtubule-based structures and, ultimately, changes in cellular morphology as those observed in neurite outgrowth.

Growth Factor Receptors and GPCRs

Several GFs mediate cell signaling through GPCRs. The convergences of GPCRs and various receptor tyrosine kinase (RTK) signaling pathways have been reported. This cross talk between GPCRs and RTK pathways could be at the receptor level or at some downstream signaling pathway (Figure 1; Malarkey *et al.*, 1995; Luttrell *et al.*, 1999; Gavi *et al.*, 2006; Natarajan and Berk, 2006).

Activation of epidermal growth factor receptor (EGFR) is linked to regulation of several G protein signaling cascades including $G\alpha$, $G_{i\alpha}$, and G_{12} by direct interaction between EGFR and either GPCR or G proteins (Poppleton *et al.*, 1996; Zhang *et al.*, 2001; Piiper *et al.*, 1997; Yang *et al.*, 1991; Profrock *et al.*, 1991). GPCR-EGFR cross talk plays important

roles in endocrine systems, including the neuroendocrine regulation of reproduction and ovulation (Hsieh and Conti, 2005). In addition, transactivation of EGFR by $\alpha 1$ -adrenoceptor ($\alpha 1$ -AR) is implicated in contraction and hypertrophy of vascular smooth muscle. This process may require participation of PI3 Kinase (Ulu *et al.*, 2013).

Several studies also indicate that GPCR and G proteins are required in some PDGF signaling pathways, such as PDGF-induced ROS production, endocytosis, and cell migration (Hobson *et al.*, 2001; Freedman *et al.*, 2002; Alderton *et al.*, 2001). S1P1 (sphingosine1-phosphate) receptor, a GPCR that plays a role in regulation of smooth muscle cell migration, proliferation, and vascular maturation, has also been shown to be required for PDGF-stimulated cell motility in several cell types (Pyne *et al.*, 2003; Hobson *et al.*, 2001).

Cross talk between GPCR and insulin or IGF have been reported in many cell types (Yang *et al.*, 1991; Rozengurt *et al.*, 2010). For example, G_i has been shown to interact with insulin and IGF receptors (Profrock *et al.*, 1991; Hallak *et al.*, 2000). Both $G_{i\alpha}$ and $G_{\beta\gamma}$ were shown to be involved in IGF-I-mediated mitogenic signal pathways (Dalle *et al.*, 2001). $G_{q\alpha}$ was also shown to play a role in insulin-induced glucose transport in adipocytes (Imamura *et al.*, 1999). Basic fibroblast growth factor

Figure 1 Model showing cross talk between GPCRs and RTK pathways. Ligand binding to either GPCR or RTK induces (1) direct interaction of the receptors, (2) direct interaction of G proteins to the RTK, or (3) to the downstream signaling molecules. (4) Endocytosis of GPCR may also be required to link GPCR to RTK signaling pathways. (5) Cross talk might also occur at downstream signaling pathways. GF, growth factors.

(bFGF) was shown to stimulate adenylyl cyclase by coupling to G_{α} but inhibit NADPH oxidase via $G_{\beta\gamma}$ (Krieger-Brauer *et al.*, 2000). In addition, $G_{\beta\gamma}$ was shown to be linked to FGF inducing skeletal muscle differentiation through ERK1/2 activation (Fedorov *et al.*, 1998). Likewise, $G_{\alpha q}$ and $G_{\beta\gamma}$ have been shown to be involved in cell migration and proliferation regulated by vascular endothelial growth factor (VEGF) (Zeng *et al.*, 2002a,b, 2003). In neurons, nerve growth factor (NGF) was shown to induce neuronal differentiation and neurite outgrowth through G protein cross talk, which will be discussed in more detail in the next section (Sarma *et al.*, 2003).

In addition to RTK, the WNT pathway is also known to involve activation of a GPCR, (frizzled) and the subsequent engagement of cellular growth pathways. For the most part, these involve translocation of β -catenin to the nucleus and subsequent gene activation. Curiously, despite exhaustive search, the nature of the G protein involved has not been identified. WNT may represent 'biased agonism,' or the engagement of an arrestin-dependent, G protein independent, pathway following activation of a given GPCR. On the other hand, activation of pertussis-toxin sensitive G proteins (G_i / G_o) has been reported to accompany activation of frizzled by WNT (Kilander *et al.*, 2014).

NGF Induces Neurite Outgrowth through G Protein

NGF promotes G_{α} translocation and interaction of tubulin and G_{α} without changing the expression of G_{α} in PC12 pheochromocytoma cells. In the presence of NGF the association of G_{α} (Kobilka and Schertler, 2008) with microtubules in the cellular processes is increased (Sarma *et al.*, 2003), suggesting an interplay between GPCR and RTK, which might be another possible mechanism of NGF inducing neuronal differentiation and neurite outgrowth.

In addition, expression of the dominant-negative G_{α} in PC12 cells greatly inhibited neurite outgrowth, whether evoked by expression of mutationally active G_{α} or by NGF (unpublished data). While the degree of inhibition was greater for the activated G_{α} than for NGF, neurite outgrowth evoked by the latter was inhibited, suggesting that there is some cross talk between G_{α} - and NGF-mediated events.

GPCRs, G_{α} , and Neurite Outgrowth

One recent study showed that activation of G_{α} and subsequent translocation from the plasma membrane resulted in G_{α} decoration of microtubules (Yu *et al.*, 2009). This occurred subsequent to either GPCR activation or direct activation of G_{α} with cholera toxin. Mutationally activated G_{α} behaved in a similar fashion and all elicited neurite outgrowth in PC12 pheochromocytoma cells. Only the activated (GTP-bound) conformation of G_{α} bound to microtubules, but the binding did not discriminate between GDP- and GTP-conformations of tubulin. Curiously, forskolin, which activates adenylyl cyclase and increases cAMP did not promote translocation of G_{α} , but did increase neurite outgrowth. When this was further examined using PC12 cells deficient in PKA, it was established that there was both a cAMP dependent and a cAMP independent component to neurite outgrowth elicited

by activation of GPCR and subsequently G_{α} (Yu *et al.*, 2009). In order to effect neurite outgrowth directly, it appeared that G_{α} bound directly to microtubules subsequent to translocation from the membrane. So, G_{α} acted directly as a 'second messenger' for the relevant GPCR.

Mechanisms for G_{α} -Induced Neurite Outgrowth

Microtubules are one of the important components of the cytoskeleton and are involved in many cellular processes including neurite formation and outgrowth. Structurally, microtubules are linear polymers of α - and β -tubulin. Structures of α and β tubulin are similar and they both bind GTP. However, GTP on α subunit is buried between the two subunits (α and β), while the GTP on the β subunit is exposed to solution. Therefore, only the β tubulin is able to hydrolyze GTP or exchange GDP for GTP (exchangeable). This hydrolysis occurs as a result of intrinsic GTPase activity of tubulin, which is activated during the process of polymerization upon addition of another tubulin dimer (Carlier and Pantaloni, 1983). Microtubules are highly dynamic and this dynamicity is based on an intrinsic property of tubulin capable binding, exchange, and hydrolysis of guanine nucleotides. Therefore, tubulin GTPase activity is a major determinant of microtubule polymerization and dynamics (Carlier, 1982).

After G_{α} is activated, it internalizes and binds directly to tubulin at the plus end of microtubules. Upon binding to tubulin, G_{α} stimulates hydrolysis of tubulin GTP (Wang *et al.*, 1990). Activated G_{α} stimulates tubulin GTPase with an EC_{50} of 1.2 μ M (Yu *et al.*, 2009). This suggests noncooperative activation of tubulin GTPase by G_{α} , and is consistent with a 1:1 stoichiometry between the two proteins (Dave *et al.*, 2011). This stimulation of tubulin-GTP hydrolysis results in an increase in microtubule dynamics (Yu *et al.*, 2009). Activated G_{α} increases microtubule dynamics by increasing the growing rate, the shortening rate and the catastrophe frequency, the frequency of transition from growth to shortening (Roychowdhury *et al.*, 1999; Yu *et al.*, 2009; Dave *et al.*, 2011).

Association between G Proteins and Tubulin

Several studies both *in vitro* and *in vivo* suggest direct interaction between G proteins and tubulin (Rudolph *et al.*, 1977; Kennedy and Insel, 1979; Rasenick *et al.*, 1981; Yan *et al.*, 1996). G_{α} , $G_{\alpha 1}$, and $G_{\alpha q}$ all show association with tubulin but other G protein alpha subunits, most notably $G_{\alpha t}$ (transducin) do not bind (Wang *et al.*, 1990). This allowed comparison of sequences in peptide and creation of a model for the binding interface for the tubulin- G_{α} complex (Layden *et al.*, 2008; Dave *et al.*, 2011). However, the difference between G_{α} and other G proteins is that the active conformation of G_{α} is required for tubulin interaction. GPCR stimulation by agonists or direct activation of G_{α} by cholera toxin causes translocation of G_{α} from plasma membrane to cytoplasm and microtubule networks (Yu and Rasenick, 2002). Note that since the only G_{α} that internalizes after activation is G_{α} (Allen *et al.*, 2005; Wedegaertner, 2012), this is likely the most relevant G protein to GPCR-mediated neurite outgrowth. Curiously, G_{α} , like most G protein alpha subunits has an intrinsic GTPase that would be

Figure 2 Translocation of $G_s\alpha$ from membrane to cytosol and association with microtubule plus end. Activated $G_s\alpha$ induces microtubule dynamics and increases neurite outgrowth. (1) Agonist binds to GPCR and promotes exchange of GDP for GTP on $G_s\alpha$, conferring the activated conformation to that G protein. (2) $G_s\alpha$ translocates to lipid rafts, where it is internalized, some of it associating with microtubule plus ends and activating the intrinsic tubulin GTPase. This hydrolyzes the GTP 'cap,' making, decreasing microtubule stability and increasing microtubule dynamics. (3) Greater microtubule dynamics increases neurite branching and neurite outgrowth. GPCR, G protein-coupled receptor; Ag-agonist; AC, adenylyl cyclase; α_s , alpha subunit of Gs; $\beta\gamma$, G protein beta/gamma subunits.

expected to hydrolyze rapidly GTP and convert $G_s\alpha$ to the GDP conformation, which does not bind to tubulin. Von Zastrow and colleagues have demonstrated, using conformation-sensitive nanobodies, that internalized $G_s\alpha$ retains the active, GTP-bound conformation (Irannejad *et al.*, 2013). This is consistent with GPCR/ $G_s\alpha$ -driven increase in microtubule dynamics and subsequent neurite outgrowth.

$G\beta\gamma$ subunits have also been shown to translocate to the cytosol following activation of certain $G\alpha$ (Jin *et al.*, 2000; Popova and Rasenick, 2003) and it appears that $G\beta\gamma$ binds to microtubules along a regular pattern, not unlike that seen with microtubule-associated proteins (Roychowdhury and Rasenick, 1997). Just as the transducin α subunit does not bind tubulin, the $G\gamma$ subunit most closely associated with transducin, $G\gamma 1$, does not bind tubulin. This appears due to the requirement that the $G\gamma$ be geranylgeranylated rather than farnesylated (as is the case with $G\gamma 1$) (Roychowdhury and Rasenick, 1997). The translocation to the cytosol of $G\beta\gamma$ follows activation of Gq-coupled receptors (m1, m3) that also evoke microtubule depolymerization due to increased Ca^{2+} . It appears that there is a continuum between microtubule depolymerization by Ca^{2+} and stabilization by $G\beta\gamma$ – both responding to the same external signal (acetylcholine) (Popova and Rasenick, 2003, 2004).

Conclusion

This article suggests interplay between GFs, GPCRs, and G proteins, which is crucial for several cellular responses and physiological functions. It also indicates a direct role for the G

protein, $G_s\alpha$ in regulating both microtubule dynamics and in regulating microtubule-dependent cellular outgrowth. Further, it demonstrates a direct role for G proteins and the GPCRs that activate them in the regulation of both microtubule dynamics and the modulation of cellular and neuronal morphology (Figure 2). Much remains unknown about both the interactions between GPCRs and growth factor receptors and the interface between their downstream signaling pathways. Ideally, this will be elucidated soon.

Introduction

Cellular survival depends on an organism's ability to respond and adapt to extracellular signals in its environment. Signal transduction is, therefore, an important biologic process, allowing cells to react to a variety of these extracellular stimuli and respond adaptively. Guanylyl cyclases (GCs) comprise one ubiquitous class of signaling enzymes that sense and transduce extracellular signals to intracellular signaling cascades through production of the cyclic nucleotide second messenger known as cyclic guanosine monophosphate (cyclic GMP or cGMP). In turn, cGMP activates cGMP-dependent protein kinases (PKGs), cGMP-gated ion channels, and other downstream targets, which potentiate cellular responses. Importantly, these cGMP signaling cascades are involved in a wide array of diverse cellular processes including neurotransmission, vasodilation, intestinal homeostasis, and retinal phototransduction. These myriad functions underscore the near universal distribution of cGMP signaling in mammalian biology.

There are several members of the GC family of receptors, permitting significant structural and functional diversity. Importantly, these proteins all generally share a conserved dimeric catalytic domain, but are otherwise structurally diverse (Figure 1). Soluble GCs (sGCs) are cytoplasmic proteins that are responsive to intracellular nitric oxide (NO), a radical, which readily crosses the cell membrane to interface with this receptor. Particulate GCs (pGCs) are transmembrane receptors, primarily for extracellular ligands, that produce intracellular cGMP. These membrane-spanning proteins contain α helical transmembrane domains similar to those of the growth factor superfamily of receptors.

Although much of the structure and function of GCs was elucidated decades ago in a series of seminal studies, more recent work has uncovered novel physiological and pathophysiological roles for GCs in a variety of previously uncharacterized tissues and disease processes. Here, we summarize GC structure and function and provide an overview of the translation of this biology into understanding human physiology and disease and development of new therapeutics.

Soluble GCs

In the 1970s, a series of paradigm-shifting reports led to the identification of a novel signaling pathway consisting of NO-dependent induction of cGMP signaling through sGCs (Arnold *et al.*, 1977; Murad *et al.*, 1978). This original work was awarded the 1998 Nobel Prize in Physiology or Medicine and was focused primarily on the sGC-mediated signaling cascade as a mechanism of smooth muscle relaxation. This work resulted in clinical strategies for, as well as mechanistic insights into, the use of organic nitrates and nitrites to induce vasodilation for angina pectoris.

Six years after GCs were first described in 1969 (Hardman and Sutherland, 1969; White and Aurbach, 1969), efforts to characterize their subcellular location demonstrated enzymatic activity both in cytoplasmic as well as membrane-associated tissue homogenate fractions. The cytoplasmic GCs were named sGCs, whereas the membrane-bound GCs were termed pGCs. The catalytic activities of both particulate and soluble GCs are dependent on a dimerized structure (Figure 1). sGCs exist as heterodimers of homologous subunits designated as α and β . The most commonly studied isoform of sGC is the $\alpha1\beta1$

Figure 1 Mammalian GC domain structure. GCs can be subdivided into two broad groups: soluble and particulate. Soluble GCs are cytoplasmic proteins, which bind the intracellular ligands NO and CO and produce intracellular cGMP. In contrast, particulate GCs are transmembrane proteins, which bind extracellular ligands and transmit signals internally via intracellular cGMP production. ANPCR possess an extracellular natriuretic peptide-binding, but lacks intracellular catalytic domains, and acts primarily as a natriuretic peptide-clearance receptor.

protein, which is nearly ubiquitously expressed and possesses physiologically relevant ligand-binding and catalytic activity. However, the alternative isoforms $\alpha 2$ and $\beta 2$ also exist. The $\alpha 2$ subunit expression is limited to select tissues, including brain, lung, colon, heart, spleen, uterus, and placenta. The $\alpha 2\beta 1$ heterodimer resulting from this subunit has been shown to possess ligand-binding and catalytic functions similar to $\alpha 1\beta 1$. Interestingly, there is a splice variant of $\alpha 2$ known as $\alpha 2i$, which contains an in-frame insertion of 31 amino acids in the catalytic domain. This subunit is not only functionally inactive, but acts as a dominant-negative protein and is putatively involved in negative regulation of sGCs. The $\beta 2$ subunits have very limited expression, with messenger RNA (mRNA) studies localizing it mostly to the kidney. While the functions of $\beta 2$ subunits remain undefined, studies have shown that overexpression of $\beta 2$ results in catalytic activity when expressed in the absence of $\alpha 1$ and $\beta 1$ units, suggesting the possibility of homodimers of $\beta 2$ subunits.

Architecturally, each sGC subunit consists of four domains (Figure 1): an amino-terminal NO-binding heme-containing domain, a Per/Arnt/Sim (PAS) domain, a coiled-coil domain, and a carboxy-terminal catalytic domain. The different sGC α and β subunits isoforms possess more variability at the amino-terminus, whereas the carboxy-terminal catalytic domain is highly conserved, suggesting distinct regulatory functions amid conserved catalytic function.

The amino-terminal ligand-binding domain contains a heme prosthetic group that is indispensable to its function. Structurally, there is a histamine residue at position 105 that serves as a heme ligand in the $\beta 1$ subunit. This domain belongs to a larger family of proteins known as the heme-nitric oxide and oxygen binding proteins (H-NOX). In the context of sGCs, the heme domain can bind NO as well as carbon monoxide (CO). However, while other members of the H-NOX family exhibit O₂ binding, the heme domains in sGCs do not.

The carboxy-terminal domain of sGC is catalytic, and this domain in α and β subunits of sGC share significant homology, not only with one another, but also with pGCs. These catalytic domains have now been localized in sGC to residues 467–690 in the $\alpha 1$ subunit and 414–619 in the $\beta 1$ subunit. Several residues are critical to catalysis, reflecting their binding of Mg²⁺ ions, which act catalytically in several ways, activating both the 3'-hydroxyl and the α -phosphate in the guanine nucleotide, as well as stabilizing the β and γ phosphates on both substrate and product. Additional residues are important in orienting the ribose ring ($\beta 1$ N548), base recognition ($\beta 1$ E473 and C541), and interaction with nucleotide triphosphate ($\alpha 1$ R573 and $\beta 1$ R552).

The central region of sGC contains the PAS and coiled-coil domains. The exact function of these domains remains undefined, though they are generally thought to facilitate heterodimerization of sGC subunits. Indeed, PAS domains are regularly involved in protein-protein interactions, a function consistent with that hypothesis. Interestingly, the coiled-coil domain shares no homology with any known protein in the National Center for Biotechnology Information protein database. Despite the uncertainty regarding the central region (PAS and coiled-coil domains) of sGC, multiple reports have provided indirect evidence for the putative dimerization function of this region, an increasingly accepted model of its function.

NO binding to sGC is a well-studied interaction given its indispensability to sGC function. This interaction is fast (occurring in milliseconds) and potent with a 50% effective concentration (EC₅₀) of 45 nM. The heme prosthetic group of sGC associates with an axial histidine residue, H105, to form a five-member ring in the amino-terminal region, which binds NO. Upon NO binding, this H105 is displaced, and a new five-member ring is formed with the NO in the fifth position. CO gas also can bind and activate sGC, but with 100-fold lower affinity, and so the physiological role for this phenomenon is unclear.

Importantly, the source of sGC-activating NO is another class of enzyme known as nitric oxide synthase (NOS). Endothelial NOS (eNOS) is produced by endothelial cells and regulates cardiovascular homeostasis, including blood pressure. Indeed, eNOS-deficient mice exhibit a phenotype of hypertension. Another isoform, neuronal NOS (nNOS), also is involved in vasodilation in the nervous system. Interestingly, nNOS-deficient mice are characterized by increased aggression and abnormal pyloric sphincters, but have normal blood pressure. These findings suggest an involvement of the nNOS-sGC cascade in complex processes beyond vascular control in the nervous system.

The best-characterized function of sGC is the vasodilation of vascular smooth muscle cells (SMCs). In this process, eNOS is activated in endothelial cells, producing NO that diffuses to neighboring vascular SMCs. In SMCs, NO induces sGC production of cGMP, activating PKG, reducing levels of pro-contractile Ca²⁺ ions, as well as desensitizing cells to Ca²⁺. Modulation of Ca²⁺ levels is accomplished by increasing Ca²⁺ efflux, sequestering Ca²⁺ in the sarcoplasmic reticulum, and decreasing the mobilization of Ca²⁺. Reduced intracellular Ca²⁺ levels induce SMC relaxation leading to vasodilation.

Prior to elucidating the NO-sGC molecular mechanism of cross-talk between endothelium and vascular smooth muscle, organic nitrates which are enzymatically converted to NO in cells were exploited therapeutically in the clinical setting for more than 150 years to treat cardiovascular disease including angina pectoris. These clinical strategies have historically included nitroglycerine, but as knowledge of sGC and its associated vasodilating agents increased, so too did inquiry into additional clinical strategies for this pathway. Inhalational NO is now approved for treatment of pulmonary hypertension in infants, and other applications are being investigated. The list of potential pharmacologic agents influencing the sGC signaling cascade also has been expanded to include phosphodiesterases (PDEs) as targets, described below.

pGCs

Unlike sGC, which is comprised of a heterodimer of α and β subunits, pGCs exist and function as homodimers. Similarly, while sGC is activated upon binding NO, pGCs produce cGMP in response to extracellular peptide ligands (GCA, B and C) or intracellular calcium flux (GCE and F). Also, unlike sGC, seven different isoforms of pGCs exist in mammals (named GCA-GCG in order of discovery) and all but GCD and GCG are expressed in humans. GCA, GCB, and GCC are activated by the binding of specific peptide ligands to their amino-terminal extracellular domain (Figure 1). GCG and GCD genes have

been inactivated to become pseudogenes in humans and all primates, respectively. In rodents, GCD is expressed in olfactory neurons and may participate in sensing cues for hunger and thirst, while the tissue distribution, ligand, and function of GCG remains undefined. Like GCA-C, GCE and GCF also possess putative extracellular domains, but no extracellular ligands have been identified for these proteins. Instead, their activity is controlled by intracellular GC activating proteins (GCAPs) that sense light-induced changes in intracellular Ca^{2+} levels.

General Structure of pGCs

In 1989, the first pGC cloned was from sea urchin testis complementary DNA (cDNA), enabling subsequent screening for homologous genes in mammalian tissues. This resulted in the discovery of seven unique mammalian pGC genes, five of which are expressed in humans. At the structural level, these proteins are largely similar: all are composed of a single polypeptide chain of approximately 1050 amino acids, which encode the protein's ligand-binding domain, transmembrane domain, regulatory sites, and the catalytic domain (Figure 1). Slightly less than half of this sequence (about 500 residues) is devoted to the extracellular amino-terminal ligand-binding domain. This portion of the molecules exhibits the lowest degree of homology between the different pGCs, consistent with the observed differences in ligand-binding characteristics of the different isoforms. A domain of 21–25 hydrophobic amino acids spanning the plasma membrane is followed by an intracellular kinase homology domain (KHD), which is composed of approximately 250 amino acids. KHD does not possess kinase activity due to changes in residues necessary for kinase function, and instead plays a role in the regulation of pGC activity. pGC mutants lacking the KHD are constitutively active, and phosphorylation sites within this domain play an important role in ligand-induced desensitization of GCA and GCC.

Connecting the KHD to the catalytic domain is a sequence of about 70 amino acids called the hinge or dimerization domain. Mutations in this domain in GCE result in autosomal dominant cone-rod dystrophy, illustrating the importance of this domain in proper pGC function. The catalytic domain of pGC is responsible for mediating the synthesis of cGMP from guanosine triphosphate (GTP). This domain contains two active sites, each with three amino acids required for catalytic activity. Each active site utilizes an Asp from one monomer and an Arg/Asn pair from the other, underlying the dimer-dependence of GCs.

GCA

GCA, encoded on the first chromosome in humans, is expressed throughout the body, with particularly high expression in the vasculature, brain, liver, kidneys, adipose tissue, and lungs. Post-translational modifications include three intramolecular disulfide bonds, extracellular Asn glycosylation, and basal phosphorylation of six residues within the KHD. GCA is activated upon binding by any of the three natriuretic peptides (atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), and C-type natriuretic peptide (CNP)). ANP and BNP are released by cardiac myocytes of the atria or ventricles,

respectively, in response to increased cardiac stretch, activating GCA to reduce cardiac load. This is achieved by inducing vasorelaxation, diuresis, and natriuresis, as well as by inhibiting the fluid retention-promoting renin-angiotensin-aldosterone system (RAAS). Genetic elimination of either GCA or ANP in mice produces cardiac hypertrophy and salt-resistant hypertension. Numerous efforts have been made to target the GCA signaling pathway with ANP peptide analogs for the treatment of hypertension, congestive heart failure, and renal disease. In 1995, a full-length analog of ANP, carperitide, was approved in Japan for the treatment of acute decompensated heart failure. However, the necessity to inject the drug limits its appeal, especially considering the numerous alternative oral antihypertensive agents. The development of a small-molecule drug targeting GCA could overcome this obstacle.

GCB

GCB, also known as natriuretic peptide receptor B, is encoded on the ninth chromosome in humans. Like GCA, it is heavily glycosylated and possesses three disulfide bonds, in addition to five phosphorylation sites within the KHD. It is expressed at high levels in the brain, heart, bones, ovaries, and lungs. The primary ligand for GCB is CNP, which, despite its name, does not induce natriuresis. Instead, CNP induces endochondral ossification and is required for proper long-bone development. Indeed, the impaired bone growth resulting from homozygous GCB loss causes a rare form of dwarfism called acromesomelic dysplasia, type Maroteaux. Furthermore, overstimulation of GCB results in bone overgrowth. Together, these data suggest that GCB may serve as a therapeutic target in diseases affecting skeletal growth.

GCC

Encoded on the 12th chromosome, GCC is expressed predominantly on the apical membrane of intestinal enterocytes, where its stimulation induces PKG-dependent phosphorylation and opening of the chloride channel cystic fibrosis transmembrane conductance regulator (CFTR). Open CFTR permits Cl^- diffusion down its concentration gradient out of the cell, into the intestinal lumen. Other ion channels and transporters maintain the electroneutrality of the cell by secreting Na^+ and water into the lumen. This system manifests as diarrhea during exposure to the enterotoxigenic *Escherichia coli* (ETEC)-produced GCC superagonist heat-stable enterotoxin (ST) during traveler's diarrhea. The endogenous ligands for GCC, guanylin and uroguanylin, also are expressed in the intestine. Uroguanylin is also produced by the kidney and is present in the circulation in its prohormone form. In 2012, an ST analog Linzess (linaclotide, Ironwood Pharmaceuticals) was approved by the FDA for the treatment of irritable bowel syndrome with constipation and chronic idiopathic constipation. In addition to maintaining fluid balance, GCC plays other homeostatic roles in the intestine, suppressing tumorigenesis by regulating cell cycle progression and reducing DNA damage, in addition to maintaining intestinal barrier integrity. As a result, linaclotide is also currently undergoing clinical trials for the prevention of colorectal

cancer. Interestingly, GCC also is expressed at low levels in the hypothalamus, where it mediates a gut–brain satiety axis. Indeed, GCC-deficient mice display increased susceptibility to weight gain and metabolic dysregulation in response to chronic high-fat diet, suggesting GCC ligands as a potential therapeutic for obesity, endemic in Western diets.

Retinal GCs

GCE and GCF are expressed primarily in photoreceptor cells of the retina, playing critical roles in phototransduction. These GCs possess no known extracellular peptide ligands. Rather, their activity is regulated by intracellular GCAPs during light/dark cycles. Exposure to light activates PDE 6, hydrolyzing cGMP to GMP. Reduced cGMP levels lead to closure of the cyclic nucleotide-gated channel, CNG1 inducing hyperpolarization of the photoreceptor cell, a key step in phototransduction. CNG1 closure also reduces Ca^{2+} influx, reducing intracellular Ca^{2+} levels, resulting in GCAP activation of retinal GCs to replenish intracellular cGMP levels, resetting the system.

The importance of retinal GCs in phototransduction is revealed by retinal diseases reflecting mutations in genes encoding GCE or GCF (*GUCY2D* and *GUCY2F* in humans, respectively). Leber congenital amaurosis type 1 (LCA-1) is a rare autosomal recessive, early onset retinal dystrophy caused by null mutations in the GCE gene (*GUCY2D*). Mutations in the *GUCY2D* locus also underlie dominant cone-rod dystrophy (CORD6), however, all mutations in CORD6 are restricted to the dimerization domain of GCE. CORD6 is a progressive disease, initiating with early loss of visual acuity and color vision following degeneration of cone photoreceptor cells. Later, rod photoreceptor cell degeneration

causes progressive night blindness and peripheral visual field loss.

ANP Clearance Receptor

ANP clearance receptor (ANPCR) is a truncated isoform of GCA encoded by the human *NPR3* gene that possesses an extracellular ligand-binding domain, but lacks all intracellular domains, including the cGMP catalytic domain (Figure 1). Thus, ANPCR binds ANP, BNP, and CNP, but produces no intracellular cGMP and acts primarily as a clearance receptor for the natriuretic peptides by constitutive endocytosis. However, ANPCR regulates a variety of physiological processes in human and rodent cells through a mechanism beyond natriuretic peptide clearance. ANPCR interacts with the heterotrimeric G proteins (G proteins) G_o and G_i and activates downstream processes through G_i . Importantly, this interaction is mediated by a short (about 25 amino acid) juxta-membrane region on the carboxy-terminus of ANPCR. This domain is conserved among pGCs and contains a consensus sequence that exists in other G protein-coupled single trans-membrane spanning receptors, suggesting that other pGCs may regulate G protein-mediated signaling cascades.

PDE

Intracellular levels of cGMP are regulated not only by its GC-mediated synthesis, but also by its removal, primarily by PDE-mediated hydrolysis (Figure 2), and to a lesser degree by export into the extracellular milieu or transit to an adjoining cell. The large PDE family of enzymes catalyzes hydrolysis of

Figure 2 Intracellular cGMP regulation by GCs and PDEs. pGC receptor–ligand interaction catalyzes the conversion of GTP to cGMP, activating downstream signaling cascades via PKG. In contrast, PDEs catalyze the hydrolysis of the cGMP 3' cyclic phosphate bond, producing inactive 5' GMP from cGMP, returning cGMP levels to baseline. PDE structure is homologous to the α and β subunits of sGCs. Most cGMP-hydrolyzing PDEs are homodimeric enzymes with two catalytic centers (C) and tandem GAF-A and GAF-B regulatory domains (A and B, respectively). The C domain catalyzes the hydrolysis of cN, whereas the GAF domains play important roles in regulating PDE activity. GAF-A and GAF-B functions vary between the different PDE family members and some PDE family members lack GAF domains, but possess other regulatory elements, such as Ca^{2+} /CaM regulated domains.

the 3' cyclic phosphate bond of the cyclic nucleotides (cN) cyclic adenosine monophosphate (cAMP) and cGMP, resulting in its conversion into an inactive 5' monophosphate (Russell *et al.*, 1973; Cheung, 1970). The two classes of PDEs, class I and class II, differ in substrate selectivity. There are 11 families of class I PDEs, and each family has its own set of isomers and splice variants originating from 21 different gene products and more than 100 mRNA products. These PDEs form homodimers with unique structures, active sites, and functions. The commonality between all the isoenzymes is a 270 amino acid catalytic domain and heterogeneous regulatory domains.

The original classification of each PDE family was to organize them according to three characteristics: substrate specificity, mode of regulation, and elution order from a diethylaminoethyl (DEAE) ion-exchange column (Butcher and Sutherland, 1962). PDEs 1, 2, 3, 10, and 11 exhibit dual specificity and hydrolyze cAMP and cGMP, whereas PDEs 4, 7, and 8 selectively hydrolyze cAMP, and PDEs 5, 6, and 9 selectively hydrolyze cGMP. Each PDE possess a regulatory domain between the amino-terminus and catalytic domain, and these vary between the different isoforms. PDE1 has a Ca^{2+} /calmodulin (CaM) regulatory domain and is activated when four Ca^{2+} atoms cooperatively bind to CaM. PDEs 2, 5, 6, 10, and 11 have GAF (mammalian cGMP binding PDEs, *Anabaena* adenylyl cyclase, plant Fh1A transcription factors) domains, which regulate various aspects of PDE dimerization and activity. The name GAF is derived from the first three domains in which these were identified. PDE4 has two upstream conserved region (UCR1 and UCR2) domains. Specific isoforms of PDE4 can be phosphorylated by cAMP-dependent protein kinase (PKA), and UCR1 phosphorylation leads to a conformational change in the structure, increasing PDE4 activity. PDE8 has a PAS domain, the function of which is poorly defined, except that it is a site for ligand binding and protein interactions. All other PDEs have complements of various subdomains, such as UCR, neutralized homology repeat (NHR), PAS, and membrane association domains.

PDE isoenzymes are localized to various intracellular regions and in various tissues, allowing compartmentalized regulation of cGMP and cAMP. Like the structure, cellular location, and tissue specificity of PDEs, the downstream physiological effects of PDEs vary greatly. PDEs regulate cardiac functions, adrenal steroidogenesis, the male erectile response, and phototransduction, and are clinically associated with asthma, erectile dysfunction, chronic obstructive pulmonary disease (COPD), autoimmune diseases, hypertension, intermittent claudication, heart failure, schizophrenia, stroke, and depression. The goal of current clinical investigations inhibiting PDEs is to enhance the signaling cascade of cN to treat these associated maladies.

Two FDA-approved inhibitors of PDE3 are Primacor IV (milrinone), for the short-term treatment of acute chronic heart failure, and Pletal (cilostazol), for reduction of symptoms of intermittent claudication. In 2011, the PDE4 inhibitor Daliresp (roflumilast) was approved for the treatment of severe COPD associated with bronchitis, but not for patients with emphysema. Most recently (2014), Otezla (apremilast) was approved for the treatment of active psoriatic arthritis. The best known PDE inhibitors target PDE5 for erectile dysfunction, made popular with the approval of Viagra (sildenafil) in 1998. Since then, Cialis (tadalafil) and Levitra

(vardenafil), and more recently, a second-generation PDE5 inhibitor, Stendra (avanafil) in 2012, have been approved. In 2011, Cialis also was approved for the treatment of signs and symptoms of benign prostatic hyperplasia.

Importantly, the number of PDE-targeted pharmacological agents under development is increasing. PDE1 inhibitors have been developed, primarily due to its prevalence in specific regions of the brain, suggesting potential activity in targeting cognitive disorders. Two current PDE2 inhibitors are being investigated for activity in endothelial permeability and learning and memory. PDE3 has been linked to insulin and leptin signaling pathways, but no specific compounds have been identified. PDE4 inhibitors have been linked to improved long-term memory and PDE10 inhibitors have been indicated for the treatment of neurological diseases, with much focus on schizophrenia.

Conclusion

The second messenger cGMP plays critical roles in various physiologic and pathophysiologic processes from single-celled to multicellular organisms, including bacteria and humans. Intracellular levels of cGMP are tightly controlled by its synthesis and elimination, mediated by GCs and PDEs, respectively. Reflecting the broad cellular and tissue distribution of these enzymes and the myriad of processes they regulate, these enzymes are key targets for established and experimental therapeutics. However, many questions about these molecules and cGMP-dependent signaling remain unanswered. Indeed, regulation of satiety and obesity by an intestinal uroguanylin to hypothalamic GCC signaling axis was identified just 3 years ago, suggesting that many GC-mediated processes are yet to be discovered.

Tumor Necrosis Factor Receptors: A Brief Digestion

Y Lin and BP Zhou, University of Kentucky College of Medicine, Lexington, KY, USA

© 2016 Elsevier Inc. All rights reserved.

Introduction

As early as the eighteenth century, it had been noticed that occasional tumor regression occurred in patients exposed to severe bacterial infection (Coley, 1991). It is, however, not until a few decades ago when we began to unveil the mechanism underlying this occurrence and really appreciate the function of tumor necrosis factors (TNF) and their receptors (TNFR). As indicated by their names, TNF/TNFR proteins are involved in the necrotic regression of tumor mass. TNF (formerly known as TNF α) and lymphotoxin (also referred to as TNF β) were successfully isolated from immune cells in 1984 (Gray *et al.*, 1984; Pennica *et al.*, 1984), with the protein coding sequences sharing 30% homology. Their specific receptors, TNFR1 and TNFR2, were cloned and expressed in 1990 (Dembic *et al.*, 1990; Loetscher *et al.*, 1990; Schall *et al.*, 1990; Smith *et al.*, 1990). In fact, TNF and lymphotoxin are two prototypic members of the TNF superfamily (TNFSF) consisting of 19 structurally related proteins; TNFR1 and TNFR2, in the meantime, belong to the TNF receptor superfamily (TNFRSF) harboring 29 members (Bodmer *et al.*, 2002; Locksley *et al.*, 2001). Since the crystal structure of TNF β -TNFR1 was revealed in 1993, there have been more than 35 specific ligand–receptor pairs identified (Bossen *et al.*, 2006). It eventually became evident that the functions of these proteins are far beyond the scope of tumor necrosis induction. Upon activation through specific ligand binding, TNFRs initiate distinct signaling pathways mediating cell survival, proliferation, differentiation, and apoptosis.

As an integral part of the immune system, TNFR signaling plays essential roles in numerous physiological events to regulate tissue development and homeostasis. Importantly, members of TNFSF and TNFRSF participate in organogenesis and maintenance of lymphoid microarchitecture, as well as induction of humoral immunoglobulin responses (Hehlgans and Pfeffer, 2005). During intracellular bacterial infections, specific TNFR pathways become activated to promote a series of inflammatory immune responses, including differentiation and cytokine secretion of T cells, activation and inducible nitric oxidase synthase (iNOS) production of macrophages, and recruitment of inflammatory cells (Hehlgans and Pfeffer, 2005). Beyond host defense, TNFSF and TNFRSF members are involved in bone and mammary gland homeostasis, hair follicle and sweat gland development, as well as neural development (Locksley *et al.*, 2001). Not surprisingly, deregulation of TNFR pathways is associated with autoimmune diseases, inflammatory diseases, and cancer. Studies have been focused on mechanistic clarification of the complicated TNFR signaling network, as well as evaluation of members of TNFSF and TNFRSF as therapeutic targets.

Classification of TNFRSF

TNFRSF members have originally been grouped according to sequence comparisons and genomic locations of their genes.

In humans, TNFRSF genes are dispersed across 14 chromosomes, with genes of several members involved in immune function residing in chr12p13 and its paralogous region chr1p36 (Locksley *et al.*, 2001). Functionally relevant receptors with their genes locating at the same chromosome clusters are speculated to derive from a common ancestor. Recently, a structure-based classification of TNFRSF was proposed. By using the T-Coffee structure-based MSAs (multiple sequence alignments) in combination with the T-RMSD (tree based on root mean square deviation) classification algorithm, TNFRSF members were divided into three groups, according to the patterns of their cysteine-rich domains (CRDs) (Magis *et al.*, 2012). Among the three groups, type S (for small) consists of small receptors with less conserved CRDs; type L-1 members are large receptors containing N-terminal CRDs, with highly conserved loop between cysteines 4 and 5; the third group is composed of large receptors with core CRDs away from the N-terminal and can be further divided into three subgroups L-2, L-3, and L-4 based on position of the core CRD within the receptor ectodomain architecture. Remarkably, this classification is in much stronger agreement with structural and functional features of TNFRSF members and may be applied to predict the convergent evolutionary process as well as interaction specificity of members of TNFSF and TNFRSF.

Structural Basis of Ligand–Receptor Interaction

Most of TNFSF members are type II transmembrane proteins with extracellular C-terminus and intracellular N-terminus. The last 150 residues of the C-terminus constitute the TNF homology domain (THD), which is responsible for receptor binding (Bodmer *et al.*, 2002). Upon proteolytic cleavage by metalloproteinases, the extracellular domain is released from the producer cell to generate mature cytokine protein in the form of soluble homotrimer. As to TNFRSF members, they largely consist of type I transmembrane proteins with extracellular N-terminus, while the remaining members are either classified as type III transmembrane proteins with extracellular N-terminus but without signal sequence (TNFR13B, TNFR13C, TNFR17, and XEDAR), attached to the membrane through a glycosylphosphatidylinositol (GPI) linker (TNFR10C), or exist in soluble forms due to proteolytic cleavage or alternative splicing (TNFR11B and TNFR6B) (Bodmer *et al.*, 2002).

Members of TNFRSF contain up to six CRDs, with three or four copies being the most frequent configurations (Locksley *et al.*, 2001). These hallmark pseudorepeats are characterized by highly conserved cysteine residues that form one to four intrachain disulfide bridges (Smith *et al.*, 1994). This unique structure enables receptor chains to fit into the trimeric ligand furrow. In fact, the ligand–receptor interaction presents a 3:3 scaffold, that is, the ligand trimer binds symmetrically to the extracellular region of three TNFR molecules (Banner *et al.*, 1993). It was originally inferred that the ligand ‘cross-linked’

three receptor monomers to form trimer. This view had been challenged by the findings that several TNFRs could oligomerize without presence of ligand (Chan *et al.*, 2000; Siegel *et al.*, 2000). Indeed, ligand-induced receptor trimerization would make possible the random assembly of 'mixed' receptor molecules, as the ligand–receptor recognition is not on a one-on-one basis, and this mess-up could interfere with downstream signaling (Chan, 2007). Of note, later findings indicated that TNFRs including TNFR1, TNFR2, TNFR5, TNFR6, TNFR10A, TNFR10B, and TNFR10D each contains a PLAD (pre-ligand binding assembly domain) within the first CRD, which favors ligand-independent, homotypic receptor assembly (Chan, 2000, 2007; Clancy *et al.*, 2005). This is, however, not a universal case, as TNFRs with only one or two CRDs do not require PLAD-mediated pre-assembling for ligand interaction (Hymowitz *et al.*, 2005). Pre-ligand assembly of TNFRs may hold advantage in binding ligand with higher affinity, circumventing potential signal interference, as well as preventing spontaneous receptor autoactivation.

Signal Transduction through TNFR Activation

Although the extracellular domains of TNFRs share limited homology, their intracellular regions are almost completely different, indicating their distinct biological functions. Indeed, signal transduction through TNFRs is initiated upon recruitment of various intracellular adaptor proteins. In most cases, the cytosolic tails of TNFRs contain either a 'death domain' (DD) or a TNF-receptor-associated factor (TRAF) interacting motif (Fesik, 2000; Inoue *et al.*, 2000). The DD is commonly present in a number of proteins regulating cell death; receptors containing DDs are defined as 'death receptors' (DR). These DRs are able to recruit DD-containing adaptor proteins through homotypic DD dimerization. DD-containing TNFRSF members include: TNFR1 (CD120a), FAS (CD95), TNF-related apoptosis inducing ligand receptor 1 (TRAIL-R1) (CD26, DR4), TRAIL-R2 (CD262, DR5), TRAIL-R4 (CD264, DCR2), TNF-like receptor apoptosis mediating protein (TRAMP) (DR3), and ectodysplasin (EDA) receptor (EDAR) (Hehlhans and Pfeffer, 2005). As the archetypal DR, TNFR1 dissociates from the inhibitory protein silencer of death domains (SODD) upon ligand binding and recruits TNF receptor-associated DD protein (TRADD), which subsequently recruits cellular inhibitor of apoptosis proteins 1 and 2 (c-IAP1 and 2), TRAF2, and receptor-interacting protein kinase 1 (RIP1). The E3 ligases TRAF2/cIAP can ubiquitinate RIP1, which then engages downstream signaling cascades to activate the pro-survival NF- κ B pathway (Li *et al.*, 2013). In addition, TRAF2 can activate ASK1, a mitogen-activated protein kinase kinase kinase (MAPKKK) and initiate a kinase cascade to eventually activate c-Jun N-terminal kinases (JNK) pathway mediating cell cycle progression and anti-apoptosis (Ichijo *et al.*, 1997). In a different cellular scenario when ubiquitination of RIP1 is removed, it tends to form complex with TRADD, Fas-associated DD protein (FADD) and pro-caspase 8 (Feoktistova *et al.*, 2011; Tenev *et al.*, 2011). It is believed that TNFR1 endocytosis and this secondary complex formation are inseparable events (Schneider-Brachert *et al.*, 2004). Within the new complex, pro-caspase 8 becomes activated to cleave and inactivate RIP1

and its family member RIP3, eventually leading to cell apoptosis characterized by chromatin condensation and fragmentation, membrane blebbing, and generation of apoptotic bodies (Micheau and Tschopp, 2003; Wang *et al.*, 2008; Bertrand *et al.*, 2008). Under certain physiological conditions such as viral infection, the functions of caspases are inhibited, and RIP1/RIP3 form the necrosome to initiate caspase-independent programmed necrosis, characterized by cell clumping and swelling, membrane rupture, and organelle degeneration (Cho *et al.*, 2009; He *et al.*, 2009; Zhang *et al.*, 2009). Taken together, TNFR1 is a pleiotropic receptor that may either lead to pro-survival NF- κ B and JNK activation or induce programmed cell death, determined by the assembly of specific higher-order signaling complexes under different conditions.

For the second group of TNFRSF members without DD, they transduce signal through the TRAF-interacting motif (TIM). These TNFRs include: TNFR2 (CD120b), LT β R, CD27, CD30, CD40, OX40 (CD134), 4-1BB (CD137), receptor activator of NF- κ B (RANK) (CD265), Fn14 (CD266, TWEAKR), transmembrane activator and calcium-signal modulating cyclophilin ligand (CAML) interactor (TACI) (CD267), BAFFR (CD268, BR3), B-cell maturation antigen (BCMA) (CD269), herpes virus entry mediator (HVEM) (CD270), activation induced TNF-receptor (AITR) (CD357), X-linked EDA-A2 receptor (XEDAR), and the member of the TNFR family TROY (Hehlhans and Pfeffer, 2005). Typically, these TNFRs use the cytoplasmic TIMs to interact with the highly conserved C-terminal TRAF domain of TRAF family members; TRAFs then recruit other signaling molecules to induce various downstream pathways. For example, activated TNFR2 associates with TRAF2, which then recruits TRAF1, c-IAP1 and c-IAP2, with subsequent signaling ending in NF- κ B activation (Rauert *et al.*, 2010; Marchetti *et al.*, 2004). Most frequently, TNFR2 signaling leads to cell survival and proliferation. However, it could induce different cellular events including differentiation and even apoptosis, depending on which genes NF- κ B transcribes.

Although different TNFRs may mediate signal transduction independently, functional overlap and even crosstalk between two certain pathways turned out to be not unusual, which is the case for TNFR1 and TNFR2. Both receptors are able to mediate cell survival/proliferation or apoptosis, although with different preferences. When these two receptors are co-expressed in the cells, there appears to be intracellular crosstalk between the two pathways. One tentative mechanism lies in that TNFR2 can modulate TNFR1 signaling to the apoptosis route through proteasomal degradation of TRAF2 and cIAPs (Fotin-Mlecsek *et al.*, 2002). However, overexpression of anti-apoptotic proteins such as NF- κ B, FLIP, Bcl-2 and Bcl-xL or downregulation of pro-apoptotic factors such as caspase 8 may render cells refractory to programmed cell death (Jaattela *et al.*, 1995; Irmeler *et al.*, 1997; Fulda *et al.*, 2001; Orłowski and Baldwin, 2002). Unlike TNFR1 that can be activated by both membrane-bound TNF (mTNF) and soluble TNF (sTNF), TNFR2 only responds to mTNF stimulation (Grell, 1995; Krippner-Heidenreich *et al.*, 2002). More intriguingly, normal TNF binding would inhibit rather than activate TNFR2 signaling, due to the presence of a TRAF2-binding site, T2bs-C, which locates at the C-terminal of TNFR2 and negatively

regulates TNFR2-TRAF2 binding and downstream signaling (Grech *et al.*, 2005). These unique characteristics of TNFR2 add additional layers of modulation and crosstalk with TNFR1. Overall, the functional consequences would depend on cell type and activation state, conformation and expression levels of TNFR1 and TNFR2, and availability of TNF and other critical signaling molecules.

The third group of TNFRSF members contain neither DD nor TIM, therefore cannot transduce signal within the cells. However, they can act as 'decoy' receptors to compete with the other two groups of TNFRSF for ligand binding. These TNFRs include TRAIL-R3 (CD263, DCR1), DCR3, and osteoprotegerin (OPG).

The Double-Edged Sword in Cancer: Signaling through TNFR1/2 as an Example

The role of TNFR signaling in cancer biology has been at the center of a long-term debate. As two of the most studied TNFRSF members, TNFR1 and TNFR2 can initiate signaling pathways leading to either tumor regression or its malignant progression. Apparently, there are several mechanisms underlying their anticancer activities (Bertazza and Mocellin, 2010). (1) Tumor vascular damage. TNF may promote the adhesion of tumor endothelial cells to leukocytes, and their subsequent migration into local areas of inflammation for clearance. In addition, TNF may suppress the activation of Integrin- α -V- β -3 selectively expressed by proliferating endothelium cells to induce apoptosis (Ruegg *et al.*, 1998). Furthermore, the high level of nitric oxide synthase (NOS) in tumor endothelial cells may sensitize them to TNF signals (Mocellin *et al.*, 2004). (2) Stimulation of innate immune system. As the specific ligand of TNFR1 and TNFR2, TNF can induce the production of other cytokines and cytotoxic factors by macrophages and natural killer (NK) cells (Vujanovic, 2001; Mocellin *et al.*, 2003). (3) Promoting adaptive immunity. TNF may mediate tumor cell rejection by T-lymphocytes, as well as promote the maturation of CD34⁺ myeloid cells into antigen-presenting dendritic cells (Prevost-Blondel *et al.*, 2000; Poehlein *et al.*, 2003; Baxeianis *et al.*, 2000; Figdor *et al.*, 2004).

In spite of a wealth of evidence supporting the anticancer activities, signaling through TNFR1 and/or TNFR2 may promote the development and progression of cancer in certain circumstances (Bertazza and Mocellin, 2010). Mechanistically, TNF may (1) function as an autocrine tumor growth factor to activate NF κ B and MAPKs, as mentioned in the earlier section; (2) upregulate cell cycle regulators such as Ras and c-Myc and downregulate Cdk inhibitors (Tselepis *et al.*, 2002); (3) cause DNA damage and inhibit DNA repair through enhancing the production of genotoxic molecules (Jaiswal *et al.*, 2000); (4) promote angiogenesis through upregulating factors such as VEGF, VEGFR2, and IL-8 (Yoshida *et al.*, 1997); (5) enhance tumor invasion through downregulation of c-Src (Kawai *et al.*, 2002); and (6) promote tumor metastasis possibly through downregulation of VCAM-1 (Kitakata *et al.*, 2002). Additionally, polymorphisms of TNF might affect its biological function and therefore cancer risk, although studies yet to obtain conclusive results.

Defining the roles of TNFR1/2 signaling in cancer remains a challenging task, due to the pleiotropic nature of the receptors,

the variety of survival/apoptotic pathway derangement in cancer cells, and the profound influence of tumor micro-environment. Further basic mechanistic studies and clinical trials are warranted to elucidate the function and regulation of this sophisticated signaling network.

Clinical Targeting of TNFSF and TNFRSF Members: Focusing on Cancer Immunotherapy

In 1992, the first TNF inhibitor entered clinical trial. Since then, a number of biologics targeting TNFSF and TNFRSF members have been developed (Croft *et al.*, 2013). For example, chimeric monoclonal antibody infliximab (Remicade; Centocor Ortho Biotech), human monoclonal antibodies adalimumab (Humira; Abbott), golimumab (Simponi; Centocor Ortho Biotech), denosumab (Prolia/Xgeva; Amgen), and belimumab (Benlysta; Human Genome Sciences/GlaxoSmithKline), as well as TNFR2-Fc fusion protein etanercept (Enbrel; Amgen/Pfizer) are clinically approved antagonists for treatment of autoimmune and inflammatory diseases. Biologics can also be specific antibodies lacking Fc region, such as Certolizumab pegol (Cimzia; UCB), a pegylated Fab fragment against TNF; and ESBA105, a humanized scFv against TNF. Other categories of biologics include naturally selected or engineered antibodies with enhanced cytotoxicity to eliminate pathogenic cells expressing specific TNFRSF members, RNA aptamers to TNFRSF molecules, and TNFSF ligand recombinant constructs.

The diverse biological functions of TNFR signaling ranging from selective induction of cell death to stimulation of effective immune responses make it a promising target for cancer immunotherapy. Earlier studies based on *in vitro* assay and mouse models showed that TNF has potent antitumor activity through the apoptotic TNFR1 pathway (Sugerman *et al.*, 1985; Old, 1988). However, since TNFR1 is universally expressed, systemic administration of TNF would cause severe toxicity due to its lack of tumor cell-binding selectivity. In the current clinical setting, TNF is administered only through locoregional delivery approaches to minimize systemic toxicity. This makes it impossible to assess the effectiveness of TNF on the overall patient survival, which depends on metastasis of tumor cells across the body that cannot be reached by locoregional treatments. In addition, signaling through TNFR1 may lead to either cell survival or apoptosis, adding another layer of uncertainty to use TNF as a single cancer therapy. Compared to TNFR1, TNFR2 is tightly regulated, with limited expression in certain immune cells, endothelial cells, and hematopoietic cells. Considering that TNFR2 activation favors the switch to the TNFR1 apoptosis pathway, and that soluble TNF can only trigger TNFR1 rather than TNFR2 signaling, TNFR2-selective TNF derivatives are developed as anticancer drugs. For example, TNC-scTNFR2 is a TNFR2 agonist designed by fusing the trimerization domain of tenascin C (TNC) to a TNFR2-specific single-chain TNF molecule to generate mTNF-like activity (Fischer *et al.*, 2011). In addition, scFv:TNF-based fusion proteins contain a TNFR2-selective TNF molecule and an antibody fragment that can specifically bind target antigen, usually associated with or overexpressed in tumor endothelial cells. Once the fusion protein becomes membrane-bound

upon antibody–antigen recognition, it will specifically activate TNFR2, which then sensitizes tumor endothelial cells to TNFR1 apoptotic signaling and results in destruction of tumor vasculature. This antibody-mediated delivery approach has been applied through targeting stromal (fibroblast activation protein (FAP)), endothelial (integrins) or cellular (EGFR and Her2) antigens (Wajant *et al.*, 2005). Similarly, derivatives of other TNFSF members, such as Fas-ligand (FasL) and TNF-related apoptosis inducing ligand (TRAIL), have also been developed (Bremer, 2013).

Furthermore, research has been focused on improving the anticancer activity of TNF. For example, various TNF analogues are designed to enhance receptor-binding selectivity; drug delivery systems are evaluated and optimized to minimize systemic toxicity without much compromising efficacy; TNF is administered in combination with NF κ B inhibitors to increase sensitivity; and TNF sensitizers such as nitric oxide and non-steroidal anti-inflammatory drugs (NSAID) are tested to increase anticancer activity (Bertazza and Mocellin, 2010). Intriguingly, evidence suggested that endogenous low-dose TNF chronically produced within the tumor microenvironment could promote cancer development and progression, in contrast to the anticancer activity of high-dose, single-shot TNF-based regimens. Therefore, upon administration of sTNF derivatives, its intracellular concentration should be carefully monitored.

On the basis of the tumor-promoting effects of TNF, the second category of therapy comprising TNF antagonists have also been developed for treatment of hematological malignancies, such as multiple myeloma, myelofibrosis, and acute myelogenous leukemia, as well as solid tumors, such as melanoma, renal cell carcinoma (RCC), and breast cancer (Du Bois *et al.*, 1997; Tsimberidou *et al.*, 2003; Szlosarek and Balkwill, 2003). Among them, humanized antibody RO5458640 against TWEAK is currently in Phase I clinical trial for treating solid tumors. Preliminary studies of etanercept on breast cancer patients have also been reported. Of the two categories of antagonists, ligand-specific antibodies bind to the antigenic epitope in the ectodomain of TNFs, whereas receptor-based antibodies bind directly to the receptor-binding region of TNFs, both of which being able to inhibit TNF–TNFR interaction.

The rationale for developing the third category of anticancer therapy is that many members of TNFRSF are costimulatory proteins that either promote B and T cell development and survival or potentiate immune responses. In this regard, agonists of these TNFRs may hold a promise as antitumor drugs. Following are a few examples. (1) CD137 (4–1BB): Monoclonal antibody urelumab (BMS-663513) has entered Phase I/II trial for the treatment of melanoma, RCC, and ovarian cancer. (2) CD134 (OX40): A mouse monoclonal antibody is in Phase I clinical trial; humanized antibodies and a fully human OX40L:IgG fusion protein have also been developed. Furthermore, OX40 agonists in combination with stereotactic radiation and/or cyclophosphamide are in Phase II clinical trial. (3) CD357 (GITR): Phase I trial of the humanized antibody TRX518 against melanoma is ongoing. (4) CD27: Human antibody SGN-75 is in Phase I trial for treating RCC and non-Hodgkin's lymphoma; CD27-expressing dendritic cells are evaluated in Phase I/II trial for treatment of

melanoma. (5) CD40: Human antibody CP-870893 is in Phase I trial treating melanoma and pancreatic cancer; chimeric antibody Chi Lob 7/4 is in Phase I trial targeting non-Hodgkin's lymphoma. (6) CD30: Chimeric antibody SGN-30 is in Phase II trial treating Hodgkin's lymphoma and Anaplastic large-cell lymphoma (ALCL). (7) CD26 (TRAILR1, DR4): Human antibody Mapatumumab/HGS-ETR1 is in Phase I trial targeting various cancers.

For the fourth category of anticancer therapy, antibodies are selected or engineered for enhanced cytotoxicity against tumor cells. Examples of these tumor cell-depleting biologics are: brentuximab vedotin (Adcetris; Seattle Genetics), a clinically approved CD30 specific chimeric antibody for treating ALCL and Hodgkin's lymphoma; SGN-75, MDX-1411 and MDX-1203, three humanized CD70 specific antibodies all in Phase I trials for treating RCC and non-Hodgkin's lymphoma; and lucatumumab/HCD122, a CD40 specific antibody in Phase I/II trial targeting various kinds of lymphoma, among others.

Collectively, a host of clinical and preclinical studies are underway to evaluate the targeting of specific TNFSF and TNFRSF members as immunotherapy of cancer, many of which having promising results. On the other side, activation of TNFR signaling may result in completely different cell fates, depending on cell types, metabolic status, and the surrounding microenvironment. Therefore, there is possibility that certain TNF/TNFR-based drug used to treat one type of cancer can increase the risk of developing another type of malignancy. Furthermore, a large part of TNFSF and TNFRSF members are not constitutively expressed, making both timing of treatment and target selection critical and challenging factors. Finally, challenges remain in inducing anticancer activities while avoiding increased susceptibility to infectious diseases or undesired inflammatory and autoimmune responses. It is advised that ubiquitous administration can have severe side effects, whereas tailored combination therapy may represent a safer and more efficient treatment strategy. All these factors must be taken into careful consideration when selecting TNF/TNFR targets as well as optimizing delivery systems.

Concluding Remarks

Challenging as it is, we are in a promising territory for the thorough appreciation and digestion of TNFR-mediated signaling with the help of contemporary molecular and cellular techniques in combination with bioinformatic approaches. With the expansion of our knowledge on the biology of TNFRSF and their ligands, the focus has widened from basic mechanistic research to therapeutic interventions at the clinical forefront. We envision the use of drugs targeting TNFSF/TNFRSF members as an important part of routine regimens for treatment of related diseases.

Glossary

Apoptosome The apoptosome is a heptameric protein complex of the intrinsic apoptotic pathway, which drives the activation of pro-caspase-9, which in turn activates pro-caspase-3. The apoptosome, consisting of Apaf1, pro-caspase-9, and dATP, is assembled following cytochrome c release from mitochondria in response to low intracellular potassium concentrations, and Bak- and Bax-induced formation of mega-channels within the outer mitochondrial membrane.

Autoimmune disease An autoimmune disease develops as a result of an immune response toward healthy tissue and substances that are regarded as foreign. The condition may affect one or more types of tissue and can affect organ function and development.

Death domain A death domain is an ~80-amino-acid protein interaction domain consisting of a bundle of six antiparallel α -helices also known as a 'death fold.' Death domains have the capacity to oligomerize with each other, thereby promoting interactions between proteins such as TNF death receptors and FADD/TRADD adaptor proteins. A death domain is found in proteins involved in apoptosis and inflammation.

Death effector domain Similar to the death domain, the death effector domain consists of a bundle of six α -helices

that fold into a 'death fold.' Death effector domains interact with each other and are found in proteins such as FADD, pro-caspase-8 and pro-caspase-10, and cFLIP.

DISC Upon ligand binding and oligomerization of death receptors, their cytosolic death domains are brought into close proximity, creating a docking site for adaptor proteins such as FADD and pro-caspase-8. This multimeric protein death-inducing signaling complex (DISC) assembles at the cell surface and relays the extracellular apoptotic signal to the cell interior, thereby inducing downstream signaling cascades.

TRAF proteins TRAF proteins are cytosolic adaptor proteins capable of interacting with and transmitting signals from members of the TNF receptor superfamily. The TRAF proteins interact with TNF receptors via a conserved stretch of amino acids within the C-terminal domain of TRAF. Seven mammalian TRAF proteins have been described to date.

TRAPS A disease caused by a mutation within the TNFR1 extracellular domain causing aggregation and retention of TNFR1 within the cell, which in turn activates NF- κ B. TRAPS is characterized by periods of high fever as well as abdominal and joint pain, rash, and inflammation in various areas of the body.

Introduction to Cell Death

In metazoans, programmed cell death, or apoptosis, is crucial for eliminating excess cells. This process occurs during neural development, the acquisition of immunity, and the maintenance of tissue homeostasis (Strasser *et al.*, 2011). Apoptosis, or the lack of it, is also a feature of degenerative diseases and cancers, respectively. In vertebrates, apoptosis mainly occurs by one of two pathways named the intrinsic (mitochondrial) and extrinsic (receptor) pathways. The intrinsic pathway, which was first identified in *Caenorhabditis elegans*, is typically engaged in vertebrates following intracellular damage or growth factor deprivation and is executed following changes to the mitochondria. The extrinsic pathway is triggered by external factors and relies on death receptors (DRs) of the tumor necrosis factor (TNF) receptor superfamily (Croft *et al.*, 2012).

DRs, a Subset of the TNF Receptor Family

Receptors of the TNF receptor (TNFR) superfamily are characterized by the presence of one to four extracellular cysteine-rich domains and comprise a family of proteins with over 25 members, many of which are involved in immunological

functions. Within this superfamily is a subgroup of eight DRs thought to have evolved 350–450 million years ago, before the divergence of bony fish and tetrapods, with a single homologous receptor found in *Drosophila* (Croft *et al.*, 2012; Igaki and Miura, 2014). The eight DRs are Fas, tumor necrosis factor receptor 1 (TNFR1), p75 neurotrophin receptor (p75^{NTR}), DR 3, DR 4, DR 5, DR 6, and the ectodysplasin-A receptor (EDAR) (Figure 1), many of which are also known by a variety of other names (see Table 1) and fall into three homologous groups (Figure 1; Sessler *et al.*, 2013). In addition to having extracellular domain homology, each DR also contains a cytosolic ~80 amino acid so-called death domain, a protein–protein interaction module that is found in over 30 cell death-inducing proteins. However only four, including the tumor necrosis factor receptor type 1-associated death domain (TRADD), Fas-associated death domain protein (FADD), EDAR-associated death domain-containing adaptor protein (EDARADD), and receptor-interacting protein 1 (RIP1), bind directly to the death domain of TNFRs (Sessler *et al.*, 2013). Highlighting their functional importance, at least one DR, and often more, is expressed in every cell of the human body. However, the function of this receptor class is not solely to mediate cell death.

Figure 1 Members of the DR family and their ligand interactions. Not depicted are the decoy receptors DcR1 and DcR2, which both interact with TRAIL. p75^{NTR} also interacts with the pro-form of neurotrophins by forming a complex with the co-receptor sortilin or SorCS2. Domains are derived from NCBI protein sequence annotations (see also Bodmer, J.-L., Schneider, P., Tschopp, J., 2002. The molecular architecture of the TNF superfamily. *Trends in Biochemical Sciences* 27, 19–26).

Table 1 Commonly used and alternative names for DRs

Death receptor	Pseudonyms
Fas	Apo1, CD95, TNFRSF6, APT
DR4	TRAIL-R1, TNFRSF10A, CD261, APO2
DR5	TRAIL-R2, TNFRSF10B, CD262, KILLER, TRICK2, ZTNFR9
TNFR1	p55, CD120a
DR3	DDR3, Apo-3, TNFRSF25, TRAMP, LARD, WSL-1
EDAR	Anhidrotic ectodysplasin receptor 1, EDA-A1 receptor
p75 ^{NTR}	NGFR, LNGFR, TNFRSF16, p75(NTR), CD271, Gp80-LNGFR
DR7	TR-7

Ligand Activation of DRs Occurs by Receptor Oligomerization

The DRs are typically activated upon binding of ligands to their cysteine-rich repeats. The ligands are not always soluble molecules; they can also be membrane-bound and expressed on the surface of other cells, which activates the TNFRs *in trans*. Classically, upon binding ligands, the DRs oligomerize, bringing together the death domains, and recruiting other death domain-containing adaptor proteins, thereby facilitating signal transduction. Based on the trimeric crystal structure of TNFR1 and one of its ligands TNF β /lymphotoxin (LT) α (Banner *et al.*, 1993), the prevailing view is that activated TNFRs are trimers. However, this view is being challenged by more recent data. Unlike receptor kinases where dimerization

of two independent receptors is induced by ligands to activate the receptor–ligand complex, preformed inactive complexes exist at the cell surface for many of the TNFR family members (including TNFR1, Fas, DR4 and 5, and p75^{NTR}) (Chan *et al.*, 2000; Siegel *et al.*, 2000; Papoff *et al.*, 1999; Clancy *et al.*, 2005; Sykes *et al.*, 2012). Furthermore recent work has highlighted the fact that TNFRs may signal as symmetric dimers (p75^{NTR}), or as asymmetric trimers (DR5), with preformed receptor cluster rearrangement from trimer to dimer, or visa versa, being induced by ligand binding (Sessler *et al.*, 2013). Moreover, ligands may drive large-scale clustering of receptor complexes located within lipid microdomains into macrodomains to mediate signaling outcomes (Sessler *et al.*, 2013). There is currently no consensus on this issue, and more work needs to be performed to clarify the mechanism by which ligands result in receptor activation.

DR Signaling is Mediated by Protein Interactions

DR activation typically results in signal transduction pathways that are mediated by protein–protein interactions rather than phosphorylation cascades. Indeed phosphorylation of TNFR members has been relatively poorly studied, with receptor phosphorylation appearing to be more regulatory than required for function (Sessler *et al.*, 2013). Once receptors are clustered and activated, signal transduction occurs via the association of intracellular partners with binding sites within both the death domains and the other cytoplasmic domains of the DRs, thereby allowing additional signaling proteins to interact. Indeed, the variety of cytoplasmic interacting partners

underpins the capacity of DRs to activate multiple alternative signaling pathways, sometimes of opposing function (e.g., survival or proliferation versus cell death), depending on the cellular circumstance. Although each of the eight DRs can activate apoptosis, promoting cell death is not necessarily a receptor's main function. The pleiotropic biological outcomes of the DRs are further regulated by receptor internalization, ubiquitination, shedding/regulated intramembrane proteolysis, and other posttranslational modifications, including palmitoylation.

DR Signaling Activates Multiple Signal Pathways

This section will highlight the three signal transduction pathways frequently activated by DRs. The signaling and functional outcomes for each receptor are provided in more detail in the subsequent sections.

Extrinsic Apoptotic Pathway

The canonical apoptotic pathway (Figure 2(a)) is mediated by the binding of the death domain-containing protein FADD to the death domain of the DR Fas, DR4 or 5. In turn, pro-caspase-8 is recruited to the complex via the FADD death effector domain (DED), thereby forming the death-inducing signaling complex (DISC). DISC formation can autocatalyze the cleavage and thereby activation of caspase-8 (as well as pro-caspase-10 in humans) which activates downstream caspases such as caspase-3 and caspase-6. Caspases are endoproteases that cleave vital cellular proteins, and their caspase-mediated degradation triggers apoptotic processes, including membrane blebbing, nuclear condensation, and DNA fragmentation.

Caspase-8 can be inhibited by the inhibitor of apoptosis protein (IAP) and cellular inhibitor of apoptosis protein (cIAP).

Intrinsic Apoptotic Pathway

The second apoptotic pathway is the mitochondrial death pathway (Figure 2(b)), which is typically activated by environmental stressors. However, it can also be used by DRs as an amplification loop, and appears to be the main death signaling mechanism for p75^{NTR} (Murray *et al.*, 2003). This pathway is genetically conserved between mammals and worms (Metzstein *et al.*, 1998). Major regulators of the mitochondrial death pathway are the B-cell lymphoma 2 (Bcl-2) family of pro-apoptotic and anti-apoptotic proteins. In particular, proteolytic cleavage of the pro-apoptotic Bcl-2 protein Bid generates the truncated variant tBid, which translocates from the cytosol to the outer mitochondrial membrane, thereby promoting oligomerization of pro-apoptotic Bak and Bcl-2 associated X-protein (Bax). Oligomerized (Bcl-2 homologous antagonist/killer) Bak and Bax can subsequently form so-called mega-channels within the outer mitochondrial membrane, allowing the release of cytochrome c and second mitochondria-derived activator of caspases (SMAC)/DIABLO into the cytosol. Here, cytochrome c complexes with apoptotic protease activating factor 1 (Apaf1), dATP, and pro-caspase-9 forming the apoptosome. Within the apoptosome, pro-caspase-9 is activated, which then cleaves caspase-3, -6, -7. Released SMAC/DIABLO further facilitates apoptosis by suppressing the IAP X-linked inhibitor of apoptosis protein (XIAP), which otherwise inhibits the activity of caspase-9. Anti-apoptotic B-cell lymphoma-extra large (BclxL) is another inhibitor of the apoptosome. Bid can be cleaved by caspase-8

Figure 2 DR signaling pathways. (a) The canonical extrinsic apoptotic signaling pathway typically used by Fas. (b) The intrinsic mitochondrial death pathway. (c) Signaling via TRADD TNF receptor-associated factors (TRAFs) and RIP.

to trigger pathway activation, thereby initiating parallel apoptotic cascades.

Non-Apoptotic Pathways

The other major pathway activated by the DR family members promotes survival, differentiation, or inflammation by activating the mitogen-activated protein kinase (MAPK)/c-Jun N-terminal kinase (JNK) and/or nuclear factor κ B (NF- κ B) (Schneider-Brachert *et al.*, 2013). These pathways (Figure 2(c)) are also evolutionarily conserved from insects to humans (Igaki *et al.*, 2002). In mammals, the pathway can be activated by TNFR-associated factor (TRAF) family members, particularly TRAF 2, 4, and 6, which bind either directly to the death domain of the TNFRs or to death domain adaptor proteins. In turn, TRAF proteins bind to RIP kinases, which also contain a death domain (e.g., RIP1) or a caspase recruitment domain (RIP2). Association occurs between TRAF and/or RIP kinases with the inhibitor of kappa B ($\text{I}\kappa\text{B}$) kinase (IKK) via transforming growth factor β -activated kinase 1 (TAK1) (Wilson *et al.*, 2009). IKK activity regulates $\text{I}\kappa\text{B}$ ubiquitination and its subsequent degradation (Chung *et al.*, 2002; Zhang *et al.*, 2010), thereby allowing nuclear translocation of nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B) to promote survival or inflammation. By a direct interaction, TRAF proteins can also regulate MEK kinases and thereby activate JNK, which promotes other cellular functions, and other regulatory kinases (e.g., NIK) (Chung *et al.*, 2002). TRAF protein signaling can be inhibited by cIAPs.

As a general rule, Fas, DR4, and 5 predominantly promote apoptosis of immune cells using FADD to bridge the activated DR with the cytosolic apoptotic machinery (Figure 2). TNFR1 and DR3 mainly control inflammatory responses by apoptotic and non-apoptotic pathways, which are mediated in the same way except that they use TRADD rather than FADD as the bridge (sometimes referred to as Complex I). DR6, EDAR, and p75^{NTR} are predominantly engaged in developmental processes, including apoptosis, and signal via the other conserved as well as receptor-specific pathways.

Function and Signaling Pathway of Each DR

The Fas Clade

Fas

Fas is widely expressed and induces apoptosis in a number of cell types, particularly within the immune system. It is important for killing pathogen-infected cells or immune cells remaining after an infection to protect against autoimmunity and tumor development. Mice homozygous for the naturally occurring lymphoproliferative (lpr) or generalized lymphoproliferative disease (gld) mutation suffer from a rearrangement of the Fas gene (Watanabe-Fukunaga *et al.*, 1992) or a point mutation in the Fas ligand gene (Takahashi *et al.*, 1994), respectively. Both conditions result in dysfunction of the Fas system, causing impaired negative selection of excess or self-reactive lymphocytes (Ramaswamy *et al.*, 2009). Accordingly, lpr and gld mice develop lpr autoimmune syndrome which manifests as lymphadenopathy, splenopathy,

and accumulation of CD4⁺, CD8⁺ T cells (Strasser *et al.*, 2009). lpr autoimmune disorders have also been found in human patients with a disruption of the Fas gene (Rieux-Laucat *et al.*, 1995) and Fas knockout mice suffer from liver hyperplasia (Adachi *et al.*, 1995).

Fas also promotes apoptosis in invading cells in immune privileged sites such as the brain, eye, placenta, and fetus. Here, Fas ligand-expressing cells induce apoptosis in Fas-expressing infiltrating cells and thereby avoid an inflammatory immunologic response (Strasser *et al.*, 2009).

As the Fas signaling system is involved in immune surveillance, Fas ligand-expressing T cells and natural killer cells suppress tumor development in Fas-bearing tumor cells. In line with this, older lpr and gld mice exhibit increased susceptibility to the development of plasmacytoid tumors (Ehrenschrwender and Wajant, 2009). However, the Fas ligand has also been identified in a variety of human tumors and is thought to play a role in the protection of cancer cells from Fas-bearing immune cells in a similar manner to that observed at immune privileged sites (Whiteside, 2007). Thus, the Fas system plays a dual role in tumor development and metastasis.

The apoptotic signal of Fas is executed upon *trans* binding of homotrimeric Fas ligand. Trimerization of Fas receptors and their intracellular death domains creates a docking site for FADD, which is required for induction of the extrinsic caspase-8-dependent apoptotic pathways (Strasser *et al.*, 2009). Fas DISC formation relies not only on Fas trimerization but also on further clustering of Fas receptor trimers (Scott *et al.*, 2009; Wang *et al.*, 2010) to induce a concomitant structural change of the Fas death domain, which allows FADD to engage DISC (Scott *et al.*, 2009). Furthermore, this pathway is only induced by membrane-bound Fas ligand (La *et al.*, 2009), possibly mediated by receptor capping into focal points within the cell membrane. This could occur by a two-step process (Grassme *et al.*, 2003). Low levels of caspase-8 activation result in enrichment of ceramide in lipid microdomains due to lysosomal acidic sphingomyelinase activity, which could lead to receptor capping within macrodomains due to the merging of the ceramide-rich microdomains. In support of this model, Fas palmitoylation (the posttranslational addition of a lipid to the receptor) is required for Fas-induced cell death (Chakrabandhu *et al.*, 2007).

Whereas the canonical death pathway is activated by Fas in so-called type-I cells (e.g., T cells) to mediate apoptosis, for apoptosis to occur in type-II cells (e.g., hepatocytes) the pathway requires amplification by the intrinsic mitochondrial pathway (Peter and Krammer, 2003; Strasser *et al.*, 2009). Thus the extrinsic and intrinsic apoptotic pathways are interconnected in type-II cells, with partial activation of caspase-8 being sufficient to cleave Bid and trigger the amplification loop. However, Fas is also capable of promoting a non-apoptotic response following Fas ligand binding in situations where the apoptotic pathway is blocked. In this paradigm, Fas has been shown to activate NF- κ B via FADD, TRAF2, and RIP1 (Kreuz *et al.*, 2004).

DR4 and DR5

The two DRs DR4 and DR5 belong to the same homology clade as Fas and promote apoptosis via a similar pathway to Fas (Figure 3(a)). In humans, the TNF-related apoptosis-inducing

Figure 3 Overview of the binding partners and downstream signaling pathways initiated by the Fas clade (a), the TNFR1 clade (b), and the p75NTR clade (c).

ligand (TRAIL) interacts with DR4 and DR5, which in turn directly interact with FADD and cause DISC assembly. Hence, activation of DR4 or DR5 can mediate both the extrinsic and intrinsic apoptotic signaling pathways (Sessler *et al.*, 2013). Signaling through DR4 and DR5 has been suggested to modulate immune responses to avoid reaction to self-reactive antigens and kill virally infected cells (Gonzalez and Ashkenazi, 2010; Collison *et al.*, 2009). Furthermore, mDR5 (the mouse ortholog to human DR4 and DR5) and TRAIL are known to suppress tumor growth and metastasis by specifically promoting apoptosis among cancer cells while sparing non-transformed cells (Grosse-Wilde and Kemp, 2008; Wu, 2009). However, recent work has indicated that DR4 and DR5 also have the capacity to activate non-apoptotic signaling pathways via the MAPK, JNK, and NF-κB pathways (Collison *et al.*, 2009; Gonzalez and Ashkenazi, 2010).

TRAIL also interacts with the two so-called decoy-receptors DcR1 (TRAIL-R3) and DcR2 (TRAIL-R4), which are both incapable of transmitting an apoptotic signal. Whereas DcR1 does not possess a cytoplasmic or transmembrane domain and is instead attached to the membrane via a glycosylphosphatidylinositol-anchor, DcR2 has a truncated and non-functional death domain and has been reported to promote activation of NF-κB (Schneider-Brachert *et al.*, 2013). However,

as the decoy receptors (DcRs) are capable of binding TRAIL they reduce DR4 and DR5 apoptotic signaling by competing for ligand binding.

TNFR1 Clade

TNFR1

Due to the widespread expression of TNFR1 and its pleiotropic nature of signaling (see below; Figure 3(b)), the physiological roles of the TNF signaling system are numerous. TNFR1 plays a major role in maintaining immune homeostasis by promoting apoptosis, cell survival, differentiation, and inflammation. Early studies with mice deficient in TNFR1 revealed a prominent role of the receptor in fighting bacterial pathogens; mice devoid of TNFR1 exhibit increased susceptibility to infection by *Listeria monocytogenes* and *Mycobacterium tuberculosis* (Rothe *et al.*, 1993; Flynn *et al.*, 1995). In line with a crucial role of TNFR1 in modulating immune responses, dysregulation of TNFR1 signaling is thought to cause several autoimmune diseases. For example, a number of mutations within TNFR1 are associated with apparent autoimmune diseases collectively known as TNF receptor-associated periodic syndrome (TRAPS), which are characterized by inflammatory attacks of variable duration (Lobito *et al.*, 2011). Dysregulation of TNF

also causes autoimmune diseases such as psoriasis, autoimmune arthritis, multiple sclerosis, and diabetes mellitus. The majority of these diseases are thought to relate to the ability of TNF to promote expression of proinflammatory genes via the NF- κ B signaling pathway (Sethi *et al.*, 2009). The proinflammatory nature of TNF signaling is also thought to contribute to cancer. Although some studies support a protective role of TNFR1 and TNF against cancer, the majority of studies have shown that TNF has the ability to promote tumor development, proliferation, invasion, angiogenesis, and metastasis (Sethi *et al.*, 2009). TNFR1 has also been shown to be involved in neuronal activity in the brain, beyond mediating inflammation (Haase *et al.*, 2008). For example, a recent study has suggested a developmental role of TNFR1 during the development of sensory neurons known as nociceptors, allowing proper perception of pain (Wheeler *et al.*, 2014).

TNFR1 is activated by binding of homotrimers of TNF or lymphotoxin- α (LT α). At the cell surface, TNFR1 recruits TRADD, which also harbors a death domain similar to that found in FADD. TRADD then recruits RIP1 and TRAF2, collectively comprising what is known as Complex I (Figure 3(b); Micheau and Tschopp, 2003). Complex I induces survival and inflammatory responses by activating the MAPK and JNK pathways. Complex I further promotes survival and proliferation by activating NF- κ B via the pro-survival kinase TAK1 (Bertrand *et al.*, 2008). Activation of NF- κ B also requires ubiquitination of RIP1 by the E3 ubiquitin ligases cIAP1 and 2 (O'donnell *et al.*, 2007; Bertrand *et al.*, 2008).

However, upon receptor internalization, FADD-mediated death signaling can also be triggered. As TRADD and FADD both interact with TNFR1 at the same site, TRADD (TRAF2 and RIP1) must dissociate from TNFR1, thereby allowing access to FADD (now known as Complex II), at which point TNFR1 promotes apoptosis rather than survival (Wilson *et al.*, 2009; Lee *et al.*, 2012). Furthermore, dissociation of TRADD can be regulated by a conformational change in the receptor (allowing formation of Complex IIA) or by ubiquitination of RIP1 (Complex IIB). The activity of complex IIA is regulated by the caspase-8 inhibitor cellular FLICE inhibitory protein (cFLIP) whereas that of Complex IIB is regulated by the levels of cIAP1 and 2 (Wang *et al.*, 2008). One hypothesis as to why TNFR1/DR3 mediate a non-apoptotic response when DISC formation occurs, whereas apoptosis mediated by DISC formation is stimulated by Fas or DR4/5, is because the latter receptors trigger a global cellular response, whereas DISC formation following TNFR1 internalization allows for compartmentalization, restricting caspase activity. Depending on the context, TNFR1-mediated DISC assembly can also alternatively promote cell survival, proliferation or differentiation as described above. The cellular outcome critically depends on the constituents of DISC and on the subcellular localization of activated TNFR1 (Schneider-Brachert *et al.*, 2013).

DR3

As the receptor with highest homology to TNFR1, DR3 signaling pathways are similarly relayed through TRADD, RIP, and TRAF2 (Meylan *et al.*, 2011). Although DR3 is capable of executing an apoptotic response, promoting apoptosis among thymocytes (Wang *et al.*, 2001a), it plays an important modulatory role in immune responses through the formation of

Complex I, by activating the MAPK, JNK, and NF- κ B signaling pathways following binding of its ligand TL1A. Specifically, DR3 co-stimulates T cells to produce a number of cytokines and promotes expansion of activated and regulatory T cells (Meylan *et al.*, 2011). It is also involved in T-cell-dependent immune responses that fight viruses and bacteria (Buchan *et al.*, 2012; Twohig *et al.*, 2012).

p75^{NTR} Clade

EDAR

The EDAR gene was identified in association with the condition ectodermal dysplasia, which is also caused by a mutation in the EDARADD (Headon *et al.*, 2001; Monreal *et al.*, 1999). The EDAR gene, which contains a polymorphism common in Han Chinese populations, is required for development of the ectoderm that gives rise to skin, hair, nails, teeth, and mammary and sweat glands, and has been most widely studied in this developmental context (Sadier *et al.*, 2014). EDAR does not interact with TRADD or FADD but, via EDARADD, signals through the TRAF family members 3 and 6 to activate JNK and NF- κ B (Figure 3(c)), thereby regulating the gene transcription required for the development of ectoderm appendages (Kumar *et al.*, 2001; Morlon *et al.*, 2005).

p75^{NTR}

p75^{NTR} is a receptor for the neurotrophin family of growth factors and mediates a wide range of cellular outcomes, predominantly in the nervous system. The best-known function of p75^{NTR} is to promote apoptosis in the developing nervous system as neurons undergo selection during the period of synaptogenesis (Miller and Kaplan, 2001). It also causes neurodegeneration after injury or in neurological conditions, including motor neuron disease and Alzheimer's disease (Haase *et al.*, 2008).

p75^{NTR} mediates cell death by the mitochondrial death pathway, as it is inhibited in cells from Apaf1- and Bax-deficient animals, and is blocked by BclxL and intracellular potassium (which inhibits cytochrome c activation of the apoptosome (Figure 2(c); Roux and Barker, 2002; Coulson *et al.*, 2004; Coulson *et al.*, 2008). Like Fas, p75^{NTR} can generate ceramide, and its cell death signaling requires lipid-rich regions of the membrane and the palmitoylation of the receptor (Dobrowsky *et al.*, 1994; Underwood *et al.*, 2008).

However, like EDAR, p75^{NTR} does not interact with FADD or TRADD (Figure 3(c)), although a dominant-negative TRADD mutant was found to inhibit p75^{NTR}-mediated NF- κ B activation (Wang *et al.*, 2001b; Sessler *et al.*, 2013). Unlike the death domains in other DRs, the p75^{NTR} death domain does not self-associate and cannot substitute for the Fas death domain, having a different tertiary structure to that of the other family members (Liepinsh *et al.*, 1997; Kong *et al.*, 1999).

Nonetheless, p75^{NTR} signals via protein-protein interactions, including binding to RIP2 and TRAF2, 4, and 6 (Roux and Barker, 2002). In addition, it interacts with NRIF and NAGE, adaptor proteins that activate JNK to promote cell death (Roux and Barker, 2002; Charalampopoulos *et al.*, 2012). Alternatively, p75^{NTR} can bind to RIP2 to activate NF- κ B, and it can also activate RhoA, to produce actin remodeling

and neurite retraction, as well as Rac1, to mediate a range of cellular outcomes. The binding sites within the p75^{NTR} death domain that underpin these various signaling pathways have recently been mapped (Charalampopoulos *et al.*, 2012).

However, the signaling pathways of p75^{NTR} are determined not only by the expressed cellular components but also by its receptor complex and ligands. Firstly, it forms a co-receptor complex with tropomyosin-related kinase (Trk) receptors, increasing their affinity for the mature neurotrophin ligands and promoting survival signaling (Skeldal *et al.*, 2011). Secondly p75^{NTR} forms a receptor–pro-neurotrophin complex together with sortilin family members (sortilin and SorCS2) to signal atrophic functions (Glerup *et al.*, 2014), and, thirdly, it combines with Nogo and the Nogo receptor to mediate neurite retraction (Kraemer *et al.*, 2014). p75^{NTR} also binds the amyloid precursor protein-derived amyloid beta peptide which induces cell death (Yaar *et al.*, 1997; Coulson *et al.*, 2009).

p75^{NTR} is further distinguished from the wider TNFR members as it uses regulated intramembrane proteolysis to regulate its signaling (Skeldal *et al.*, 2011). While regulation of cell death appears to be at least partially dependent on receptor cleavage, the ability of p75^{NTR} to regulate neurogenesis (Young *et al.*, 2007) and neural progenitor cell migration (e.g., neural crest migration) also appears to be particularly dependent on this modification (Skeldal *et al.*, 2011). In peripheral tissues, p75^{NTR} has been demonstrated to be tumorigenic (e.g., breast cancer), and to promote metastasis, specifically following intramembrane cleavage (e.g., glioma) (Johnston *et al.*, 2007; Forsyth *et al.*, 2014). However in other cases, p75^{NTR} acts as a tumor suppressor by mediating cell death in cancer cells (Molloy *et al.*, 2011).

DR6

As for other DRs, DR6 is involved in modulation of immune responses. The DR6 knockout mouse exhibits increased proliferation of CD4⁺ T cells, suggesting that DR6 is a negative regulator of CD4⁺ T cell proliferation during immune responses (Liu *et al.*, 2001). However, recent research has revealed that it also acts as a negative regulator of cell survival of neural cells such as oligodendrocytes and motor neurons during development (Nikolaev *et al.*, 2009; Mi *et al.*, 2011) and in motor neuron disease (Huang *et al.*, 2013). DR6 further regulates axonal pruning by promoting axonal degeneration (Nikolaev *et al.*, 2009; Marik *et al.*, 2013). One ligand of DR6 appears to be the amyloid precursor protein itself (Nikolaev *et al.*, 2009), which is expressed both in the brain and in peripheral tissues including blood. The signaling pathway emanating from DR6 is not well defined (Figure 3(c)), but like others in this clade it does not appear to involve caspase-8 as its central apoptotic messenger; rather DR6 triggers a caspase-dependent pathway that includes translocation of Bax to the mitochondria (Zeng *et al.*, 2012).

Summary

The DRs use three major conserved signaling pathways to mediate their functions. These are the activation of a canonical extrinsic cell death cascade, activation of the intrinsic cell death cascade, and activation via intracellular binding proteins including TRAF, RIP proteins, and transcription factors such as

NF-κB. The structural basis of activation of individual signaling proteins by these protein–protein interactions is still far from resolved. Furthermore, despite conservation of signaling mechanisms, the DRs mediate a wide array of cellular functions, often within the same cell types, which depends on the cellular environment in which the receptor finds itself. Thus regulation of DR signals is mediated by a range of post-translational changes including palmitoylation and higher order clustering of the receptors, as well as the expression of downstream signaling proteins coupled with activation by proteolysis, and/or inhibition by ubiquitination. This is an emerging area of DR research, and we encourage further exploration of this topic on a receptor-by-receptor basis.

Hedgehog Signaling in Development and Disease

D Jenkins, UCL Institute of Child Health, London, UK

© 2016 Elsevier Inc. All rights reserved.

Introduction

Key components of the hedgehog (HH) signaling pathway were first isolated as mutants affecting larval cuticle patterning in the fruit fly, *Drosophila melanogaster* (Nusslein-Volhard and Wieschaus, 1980). The HH pathway has served as a paradigm of signal transduction for over three decades, leading in our understanding of many of the fundamental mechanisms involved in intercellular communication. The generally accepted canonical model of HH signaling is largely conserved from fruit flies to humans, although differences in some of the biochemical details are apparent between species. One recent development is the finding that primary cilia are particularly important for regulation of HH signaling in higher vertebrates, and this has spawned a whole new field of investigation. The HH pathway also provides text-book examples of: (1) how a long-range morphogen is produced and secreted; (2) how transmembrane receptors are regulated by a morphogen gradient; and (3) how this can feed into transcriptional networks. Other lessons that have emerged from investigation of the HH pathway include: (4) how long-range regulatory elements determine the expression of a morphogen; and (5) the way in which a whole spectrum of anticancer and teratogenic compounds can influence various aspects of signaling mechanisms. It should also be noted that the HH pathway is a paradigm for human genetic disease. It is the only signaling pathway for which most of its constituent components are mutated in human birth defects, while somatic mutations within the pathway also give rise to specific pediatric and adult cancers. Importantly, a battery of therapeutic compounds targeting HH signaling components has been identified. Finally, very recent evidence also suggests added complexity in the HH pathway, in the form of so-called noncanonical pathways.

The Basic Mechanisms of HH Signaling

Production and Secretion of a Morphogen – The HH Proteins

By definition, a morphogen is a secreted molecule that acts at long-range. While a single HH ligand exists in fruit flies, in mammals, three homologs of *Drosophila* HH exist, which are known as Sonic HH (SHH), Indian HH (IHH), and Desert HH (DHH). Each HH morphogen is expressed as a 52 kDa precursor protein that undergoes autoproteolytic cleavage to generate an N-terminal 19 kDa protein that fulfils all patterning activities both at short- and long-range, and a C-terminal 25 kDa species (Lee *et al.*, 1994; Porter *et al.*, 1995). The C-terminal region of the unprocessed precursor serves as a catalytic domain, which cleaves the precursor protein at a highly conserved cysteine residue by an intramolecular mechanism, and this reaction exhibits concentration-independent kinetics (Porter *et al.*, 1995). Processing of HH proteins to generate an active N-terminal morphogen requires

normal cholesterol metabolism, and chemical inhibition of sterol metabolism following treatment of cells with inhibitors of cholesterol biosynthesis impedes HH precursor processing into the two smaller fragments (Guy, 2000). It is now known that HH morphogens are modified by the addition of cholesterol following autoproteolysis of the precursor protein; the newly made N-terminus of the 19 kDa morphogen becomes covalently modified by the addition of cholesterol while its C-terminus becomes palmitoylated at the same time (Lee *et al.*, 1994; Porter *et al.*, 1995).

SHH and IHH have been elegantly shown to travel at a distance of many cell diameters from their source in mice using immunohistochemistry on tissues fixed in such a way that preserves proteoglycans/glycosaminoglycans and proteins in an insoluble form (Gritli-Linde *et al.*, 2001). It is thought that addition of cholesterol is important in determining the range over which HH proteins signal. By harboring a cholesterol moiety, HH morphogens have the tendency to remain at the surface of cells that have synthesized them, owing to hydrophobic interaction between the cholesterol group and cell surface lipids. In some tissues, however, the HH-producing cell also expresses Dispatched (DISP), a sterol-sensing domain protein dedicated to the release of cholesterol modified HH ligand (Burke *et al.*, 1999). Thus, HH signaling is long-range when expressed with DISP but juxtacrine/autocrine when DISP is absent. It is thought that DISP serves to mask the cholesterol motif of HH, reducing its affinity for the cell membrane and allowing its diffusion over many cell diameters, perhaps also promoting HH oligomerization.

Given that three mammalian HH morphogens exist, each of which function in an overlapping yet distinct range of tissues, the choice of morphogen therefore represents another mechanism by which HH signaling is modulated. While SHH, IHH, and DHH bind to their receptor with equal affinity, in certain assays the concentration of each morphogen required to elicit a response can be very different (up to 60-fold); SHH has the greatest potency in most scenarios, with IHH and then DHH inducing progressively reduced effects. These relationships may also be tissue-dependent, however, because in some contexts, such as the inhibition of chondrocyte differentiation, DHH can be more potent than IHH (Pathi *et al.*, 2001). Taken together, this combined evidence shows how processing to generate an active morphogen is also involved in the tight regulation of HH signaling.

Intracellular Effectors of Signal Transduction – Transmembrane Receptors

Cells that are potentially responsive to HH morphogens express the 12-transmembrane domain receptor, Patched (PTCH), which normally serves to repress a second transmembrane protein, Smoothened (SMO) (Figure 1). Therefore, in the absence of HH morphogen, HH signaling is silenced. In contrast, binding of secreted HH to PTCH relieves its normal

Figure 1 HH signal transduction. Left – Scheme showing the logic of HH signaling. Black lines indicate activity in the absence of SHH, IHH, or DHH ligand. Red lines indicate actions following binding of ligand to the PTCH1 receptor. Middle – Scheme showing a primary cilium with central microtubular doublets anchored to the basal body and encased by membrane. In the absence of HH ligand, the PTCH1 receptor is transported into the cilium, leading to the export of SMO and transport away from the cilium in endocytic vesicles. Right – In the presence of ligand, PTCH1 no longer enters the cilium, allowing SMO to accumulate in this organelle. The box indicates two key molecules, Kinesin-II and Dync2h1 (a key component of dynein-2), which regulate anterograde and retrograde intraflagellar transport, respectively.

repression of SMO by inducing a conformational change (Ingham *et al.*, 2000; Zhao *et al.*, 2007). Extensive genetic and biochemical analyses have demonstrated the importance of protein kinases in driving changes in the subcellular localization of SMO (Jia *et al.*, 2004; Zhang *et al.*, 2005; Liu *et al.*, 2007; Zhu *et al.*, 2003; Denef *et al.*, 2000). Inhibition of PTCH repressor function by HH leads to the cell surface accumulation of SMO, a process which requires phosphorylation at a number of protein kinase A (PKA) and casein kinase I (CKI) sites in the C-terminal tail of SMO (Jia *et al.*, 2004). This intracellular domain of SMO interacts with a protein complex that includes PKA, CKI, fused (FU; another kinase), suppressor of fused (SUFI), and the kinesin-like molecule Costal-2 (COS2), which facilitates interaction of the complex with microtubules (Zhang *et al.*, 2005).

Cholesterol biosynthesis may also be important for regulation of signaling downstream of SMO. Whereas cells over-expressing SMO alone displayed low but significant levels of pathway activity, as assessed by a responsive reporter assay, treatment of these cells with cyclodextrin (an oligosaccharide that complexes with sterols) inhibited this response in a dose-dependent manner. In contrast, the HH response was unaffected by cyclodextrin treatment in cells transfected with a constitutively active oncogenic form of SMO (SMOA1; see Section Mutations in HH Pathway Components in Congenital Disease and Cancer). These results suggest that proper cholesterol biosynthesis is required for normal SMO activity as well as morphogen autoprocessing (Cooper *et al.*, 2003). These results are also relevant for human disease, because mutations in 7-dehydrocholesterol reductase (*DHCR7*), which encodes the ultimate enzyme in the production of cholesterol, cause Smith–Lemli–Opitz syndrome (SLOS). SLOS was the first inborn error of metabolism found to manifest itself as a malformation syndrome, with the range of malformations resembling those of patients with mutations in other HH pathway components (Kelley and Henekam, 2000; see Section Mutations in HH Pathway Components in Congenital Disease and Cancer).

Several novel receptors for HH morphogens, HIP, BOC, CDO, and GAS1, have also been identified more recently. These molecules were identified through combined efforts that

screened cDNA libraries for genes whose protein products facilitate binding of SHH morphogen to the cell surface (Chuang and McMahon, 1999), and that used microarrays to identify genes that are up- or down-regulated in mice with mutations in HH pathway components, consistent with their being targets of HH signaling (Tenzen *et al.*, 2006) (see also the following section). These receptors bind HH morphogens, inhibiting their diffusion and possibly internalizing and degrading them, thus regulating the steepness of the morphogen gradient. In the case of BOC, CDO, and GAS1, they also promote the response of target cells to HH morphogen (Tenzen *et al.*, 2006; Martinelli and Fan, 2007; Allen *et al.*, 2007; Zhang *et al.*, 2006).

Gene Regulatory Networks Controlled by the HH Pathway – The Glioma-Associated Transcription Factors

The ultimate output of HH signaling is the regulation of gene expression, thereby translating concentration-dependent signals into geometric patterns of transcription within a tissue. In the fruit fly, the main transcription factor that mediates the HH response is known as cubitus interruptus (CI), whereas there are three orthologous proteins in vertebrates, known as glioma-associated oncogenes, GLI1-3. In the absence of a morphogen, GLI2 and GLI3 undergo proteolytic cleavage to remove the C-terminus that contains a transcriptional activator domain. The resultant truncated 89 kDa protein still contains its zinc-finger domain, and thus retains its ability to bind DNA. In this context GLI2/GLI3 act as transcriptional repressors owing to N-terminal transcriptional repressor domains. Binding of HH to its receptor and derepression of SMO leads to activation of a series of cellular processes that prevent the cleavage of GLI2/GLI3. In their full-length 190 kDa forms, GLI2/GLI3 possess C-terminal transcriptional activator domains in combination with their zinc-finger domains and thereby actively transcribe target genes. Both the mouse and human GLI2/GLI3 proteins possess an N-terminal repressor and C-terminal activator domain (Roessler *et al.*, 2005) and so are responsible for mediating the HH response. In contrast, the GLI1 protein does not possess an N-terminal transcriptional

Figure 2 Neural tube patterning by long-range SHH morphogen. Left – Scheme of the neural tube. SHH is expressed by the floor plate (red) which is secreted, generating a ventral-to-dorsal gradient. This leads to the patterning of the neural tube into distinct neural precursor domains, p3–p0. Middle – Scheme showing that this SHH gradient establishes different domains expressing specific combinations of transcription factors. Some examples are given. These transcription factors have many mutually repressive activities, thereby converting the continuous SHH gradient into distinct boundaries of gene expression and neural identity. Right – Scheme of the spinal cord showing how these precursors give rise to specific neurons following this early patterning by SHH.

repressor domain and thus is not responsive to HH signaling. While GLI2/GLI3 mediate the response to HH in most developmental contexts, the GLI1 gene is dispensable for development although it does compensate for a loss of transcriptional activation in mice lacking GLI2/GLI3 (Bai and Joyner, 2001; Bai *et al.*, 2002; Ding *et al.*, 1998; Motoyama *et al.*, 1998; Park *et al.*, 2000). As such, GLI1-mediated transcriptional activation may simply serve to amplify the response to positive HH signaling mediated by GLI2/GLI3.

The cellular localization of CI/GLI proteins is also regulated according to the concentration of morphogen through modification of nuclear localization and nuclear export signals within these proteins. At low concentrations of morphogen, a scaffold of proteins will tether any uncleaved, potentially transcriptionally active GLI protein to the cytoskeleton, preventing its entry into the nucleus. One component of this scaffold is Costal-2, and two vertebrate homologs, Kif7 and Kif27, have been identified as negative regulators of HH signaling in vertebrates. Regulation of HH signaling by these proteins in vertebrates also relates to cilia, which involves tethering of cargo to, and its transport along, the ciliary axoneme (see Section Mutations in HH Pathway Components in Congenital Disease and Cancer). Taken together, the data suggest a ‘three-response’ model for HH signaling (Hooper and Scott, 2005). In the absence of HH morphogen, GLI-repressor is formed through phosphorylation and proteolytic cleavage, thereby inhibiting the expression of HH target genes. In the presence of low concentrations of morphogen, the processing of GLI-repressor is blocked, and some target genes are derepressed, however, a fully functional GLI-activator is either not synthesized, or it is sequestered in the cell cytoplasm. Finally, if the levels of morphogen are sufficiently high, GLI-activator protein isoforms will additionally be released from the protein complex and will enter the nucleus to activate the expression of target genes. Thus a cell can initiate graded responses depending on the concentration of morphogen sensed by the cell.

Work on patterning of the embryonic neural tube has provided an exquisite example of the way in which a gradient

of GLI-transcription factor activity can feed into a gene regulatory network that determines cellular identity. The neural tube is the anlagen of the vertebrate central nervous system. Differentiation of cell types along the dorsoventral (D–V) axis of the neural tube becomes evident as distinct classes of neurons appear at different D–V positions (Figure 2). Initial work implicating HH proteins as morphogens showed that the notochord and floor plate specifically expressed SHH and served as heterologous inducers of D–V neuronal identity. The finding that SHH could substitute for these structures to induce D–V cell fates, showed that SHH acts as a long-range morphogen within the developing neural tube (Yamada *et al.*, 1993; Roelink *et al.*, 1994).

Subsequent work showed that the GLI-transcription factors elicit the response to SHH in this tissue. *Gli2*^{−/−} mice do not correctly specify the ventral-most cells in the neural tube (Ding *et al.*, 1998; Park *et al.*, 2000), while this structure is dorsalized in *Gli3*^{−/−} mutants (Persson *et al.*, 2002; Bai *et al.*, 2002; Mo *et al.*, 1997; Park *et al.*, 2000). These findings are consistent with the notion that GLI2 acts primarily as a transcriptional-activator, while GLI3 acts primarily as a repressor. In the neural tube, this is likely to be the result of differential spatial expression of *Gli2* and *Gli3* in the dorsal–ventral axis rather than intrinsically different biochemical properties. Different neuronal subtypes within the neural tube are derived from different precursor populations that express a number of homeodomain and basic helix–loop–helix transcription factors in response to SHH (Figure 2). Many of these factors act as transcriptional repressors, and a number of mutually cross-repressive interactions have been identified (Dessaud, 2008, for review). As such, following the initial expression of these factors at defined locations along the neural tube, a gene regulatory network is established. This network serves to reinforce the boundaries between different domains of transcription factor expression. As such, a continuous gradient of SHH morphogen is translated into a segmented pattern of neuronal fates via the GLI-transcription factors.

Newer Aspects of HH Signal Transduction

The Role of Primary Cilia in Regulating Mammalian HH Signaling

Analysis of mouse mutants affecting neural tube patterning has shown that primary cilia play roles in regulating HH signal transduction. Cilia are membrane-encased, microtubular extensions present on the apical surface of most cells. They consist of a ciliary axoneme, composed of nine outer microtubule doublets (Jenkins and Beales, 2013). Some cilia also have a central pair of microtubules, and are therefore known as '9 + 2' cilia, whereas others do not have a central pair and are referred to as '9 + 0' cilia. The ciliary axoneme connects at its base to a cytoplasmically located structure known as the basal body that consists of a mother and a daughter centriole. Recent evidence has now shown that there is regulated movement of both proteins, such as transmembrane receptors, and lipids into the cilium which means that the ciliary membrane composition is separated from the cell surface membrane (Rohatgi and Snell, 2010; Hu *et al.*, 2010; Kim *et al.*, 2010). Recent evidence has also identified vesicle trafficking proteins with highly specific roles in trafficking various components to cilia.

Several HH pathway components also localize to cilia in a manner that correlates with HH pathway activity. Ciliary motor proteins are separated into complexes B or A, involved in anterograde and retrograde transport, respectively. GLI3 processing is abnormal in mice with mutations disrupting these motor proteins, with an imbalance in the levels of activator and repressor forms. Furthermore, disruption of different ciliary components can affect GLI3 processing differently. It is therefore clear that different classes of ciliary trafficking proteins regulate distinct aspects of GLI processing. The mechanisms that control this are only just beginning to be understood.

Although HH signaling is highly conserved, both the mechanisms by which Ptch1 represses Smo, and those leading to the activation of the Gli-transcription factors have remained unclear, and recent evidence suggests that this may involve primary cilia. Rohatgi *et al.* (2007) have shown that Ptch1 and Smo exhibit mutually exclusive patterns of ciliary localization – in unstimulated fibroblasts Ptch1 is present within cilia but Smo is not, whereas Smo becomes localized to cilia following application of Shh protein to cells, and Ptch1 concomitantly becomes excluded from cilia. Shh was shown to bind directly to Ptch1 at the ciliary membrane, and Smo was constitutively localized to cilia in *Ptch1*^{-/-} cells. Further work has suggested that Smo is trafficked directly from the plasma membrane to the ciliary membrane via a process of lateral transport, independent of dynamin-mediated endocytosis (Milenkovic *et al.*, 2009).

β -Arrestins are also essential for trafficking of Smo into cilia following Shh treatment (Kovacs *et al.*, 2008). β -Arrestins are key regulators of receptor internalization in clathrin-coated vesicles, and this work has suggested a model whereby Smo is internalized from the plasma membrane and recycled into the cilium through interaction with the type-II kinesin motor, Kif3a. Smo is constitutively localized to cilia in cells deficient for the dynein-heavy chain protein, *Dyn2ch1* (orthologous to

the gene mutated in asphyxiating thoracic dystrophy and short rib polydactyly) (Dagoneau *et al.*, 2009; Merrill *et al.*, 2009), although these cells fail to elicit a HH response (Ocbina and Anderson, 2008; Ocbina *et al.*, 2011). Therefore, Smo translocation into cilia is necessary, but not sufficient, for HH signaling. Instead it seems that the transport of Smo, and probably also GLI proteins, through the cilium is essential to regulate HH signaling appropriately.

Noncanonical HH Signaling

Early work into HH signaling was based largely on the analysis of gene expression in response to HH signaling in body segments and wing imaginal discs in transgenic flies. It is perhaps not surprising, therefore, that the large body of work that has followed has been strongly biased toward an analysis of the transcriptional outputs of signal transduction. In recent years, biochemical analyses of the PTCH1 protein and studies of cell migration/axon guidance are collectively revealing new, transcription-independent modes of response to HH morphogen.

Based on this evidence, Jenkins (2009) defined three modes of 'noncanonical' HH signaling:

Type 1 – Signaling that involves HH pathway components but which is independent of GLI-mediated transcription. An example where transcription-independent signaling has been formally demonstrated in a fibroblast cell line was described by Bijlsma *et al.* (2007). Soluble SHH protein was shown to act as a chemoattractant when applied to cultured fibroblasts, in a manner that was dependent on SMO. However, both chemoattraction and cytoskeletal changes were observed after SHH treatment for only 10 min, a matter of hours before GLI-mediated transcriptional responses to morphogen could first be observed in these cells. More recently, similar experiments in fibroblasts and endothelial cells have indicated that this transcription-independent regulation of cell migration is mediated by direct activation of Rac1 by SMO, in turn leading to modulation of the cytoskeleton (Polizio *et al.*, 2011a,b).

Further support for this mode of signaling initially came from studies of chick neural progenitor cells cultured on Fibronectin or Laminin-1 coated plates. These cells are initially adherent, and subsequently dissociate to become migratory. When cultured on plates onto which SHH had been adsorbed, these cells largely failed to adhere. In contrast, treatment of these explants with soluble SHH protein had no effect on adherence or migration (Jarov *et al.*, 2003; Testaz *et al.*, 2001). This suggests that SHH directly interacts with the extracellular matrix of neuroepithelial cells to stabilize them within an epithelium.

Type 2 – Direct interaction of HH signaling components with other molecular pathways, as opposed to the usual indirect regulation of cellular processes by GLI-mediated transcription. One example of this mode of signaling comes from work showing that SHH and PTCH1 participate in a novel G₂/M phase checkpoint independent of other downstream pathway components. Cyclin B1 is a critical regulator of mitotic cell division, entering the cell nucleus during late G₂ phase. Through a direct protein–protein interaction involving its large intracellular loop, PTCH1 has been shown to sequester the active, phosphorylated form of Cyclin B1 at the cell

surface, thereby inhibiting cell cycle progression (Barnes *et al.*, 2001). Binding of SHH to PTCH1 leads to release of Cyclin B1, thereby allowing it to enter the cell nucleus. As such, these HH pathway components can regulate cell cycle progression in certain situations, independently of SMO or downstream pathway components.

PTCH1 has also been shown to act as a so-called 'dependence-receptor,' inducing caspase-dependent cell death when transfected into cell lines in which it is not normally expressed (Thibert *et al.*, 2003). This effect could be inhibited by treatment with SHH morphogen in a dose-dependent manner, thereby generating a state of cellular dependency on SHH ligand for survival. PTCH1 has now been shown to function as a dependence receptor through its intracellular C-terminal tail, by forming a multi-protein complex consisting of the adaptor protein, DRAL, and Caspase-9 (Mille *et al.*, 2009). Formation of this complex in the absence of SHH morphogen leads to the ubiquitination and activation of Caspase-9, in turn triggering apoptosis. Once again, this pathway is thought to be independent of SMO or the transcriptional response to morphogen.

Since the initial definition of noncanonical HH signaling, many more examples of noncanonical HH signaling have been reported and their roles *in vivo* have been studied further. However, an in-depth evaluation of each of these pathways is beyond the scope of this article.

Long-Range Transcriptional Regulation of the Mammalian *SHH* Gene – The 'Zone of Polarizing Activity Regulatory Sequence'

As shown in Figure 3, the limb bud is patterned by a gradient of SHH morphogen which is normally expressed in a very specific location posteriorly, known as the zone of polarizing activity (ZPA). This gradient controls the number and identity of the digits. The mechanisms that regulate this expression

were illuminated by the identification of noncoding mutations that cause triphalangeal thumb in humans and polydactyly in mice and cats (Hill and Lettice, 2013, for review). These mutations lie within a highly conserved 780 bp *cis*-regulator, known as the ZPA regulatory sequence (ZRS), which is located within an intron of the ubiquitously expressed *Lmbr1* gene. This element lies approximately 1 Mb away from the *SHH* promoter, making it one of the longest-range gene regulatory elements reported to date. Using mouse transgenic reporter assays, Lettice *et al.* (2014) showed that the ZRS was able to drive the expression of a *LacZ* reporter gene within the ZPA. Interestingly, by testing the ability of truncated forms of this element to drive this pattern of expression, it was found that the 5' half was essential for driving expression, while the 3' half was dispensable in these transgenic assays. However, by creating mutations within the endogenous locus, it was found that the 3' element was required for expression of *Shh* within the ZPA. Therefore, the entire ZRS is required for proper regulation of *Shh* expression. Using 3D FISH, these authors and others have shown that the 3' sequence of the ZRS is required for the ZRS to localize with the *SHH* locus, which loops out of its chromosomal territory specifically within ZPA cells (Lettice *et al.*, 2014; Amano *et al.*, 2009).

Over 20 point mutations have been identified in the ZRS in patients with triphalangeal thumb. When these mutations have been tested in the same transgenic reporter assays, several have been shown to cause ectopic expression of *LacZ* within the anterior limb bud in addition to the ZPA, which would explain why the thumb takes on the identity of a finger. This result suggests that there are repressor elements within the ZRS that somehow inhibit expression in the anterior limb bud, perhaps through binding of transcriptional repressors. Indeed, one family has been described with a duplication of the ZRS. This has been interpreted as leading to the 'dilution' of bound repressive factors, i.e., these repressors bind to both the wild-type and duplicated ZRS, thereby halving binding at the ZRS

Figure 3 HH signaling in limb developing, and the effect of mutations in a long-range gene regulatory element. Scheme showing the early limb bud (~4 weeks in human fetuses), with proximo-distal (what will become shoulder-to-finger tip) and antero-posterior (little finger-to-thumb) axis indicated. SHH is secreted from the zone of polarizing activity (ZPA) where it signals to the limb bud mesenchyme and sets-up a posterior-to-anterior gradient of positional information. Antagonism between SHH and BMP signaling (by regulating expression of the BMP antagonist Gremlin) modulates expression of Fgf ligand in the apical ectodermal ridge (AER) which in turn signals back to the ZPA and mesenchyme. Mutations in the long-range ZRS leads to ectopic expression in the anterior domain of the limb bud in addition to the ZPA, which disrupts these signaling events and altered digit number and identity.

that interacts with the *Shh* promoter and allowing some ectopic expression. Initial support for the transcription factor binding hypothesis comes from analysis of a point mutation in a polydactylous mouse strain. This point mutant form of the ZRS is bound by HnRNP U, whereas the wild-type version is not. HnRNP U also binds the 5' UTR of the *Shh* gene, and this dual interaction leads to ectopic association between the ZRS and the *Shh* promoter (Zhao *et al.*, 2009). Taken together, the current evidence suggests that the ZRS acts as a likely platform for the binding of many transcriptional repressors and activators that interact with the *Shh* promoter through long-range chromatin looping.

HH Signaling in Human Disease

Mutations in HH Pathway Components in Congenital Disease and Cancer

Most of the molecular components that regulate the HH pathway, which have been discussed in previous sections, are constitutionally mutated in human birth defects, and a number of these components are also somatically mutated in human cancers. The HH pathway is unique, being the only signal transduction pathway for which all of its core components are mutated in human disease, as summarized in Tables 1 and 2. These tables list the phenotypes associated with each of these mutations and a summary of the clinical features of each disease. As discussed above, core HH signaling components have been shown to localize to primary cilia, and their transport through cilia is essential for the proper regulation of HH signaling. Diseases associated with mutations affecting cilia are known as 'ciliopathies.' More than 100 genes have currently been found to be mutated in ciliopathies, making this perhaps the largest category of disease in terms of genetic etiology, and this number is increasing rapidly with the advent of next-generation sequencing technologies. Consistent with the central role of cilia in HH signaling, patients with ciliopathies also exhibit defects that are characteristic of abnormal HH signaling, as discussed below, in particular limb (polydactyly and brachydactyly type-A1) and heart malformations. This category of disease will not be discussed

further as it has recently been reviewed in detail (Jenkins and Beales, 2013).

As can be seen in Tables 1 and 2, different birth defects are readily attributable to the distinct roles of SHH, IHH, or DHH as the active morphogen in different tissues. For example, patients with heterozygous mutations in the *SHH* gene exhibit craniofacial defects including cleft lip/palate and a spectrum of midline defects ranging from solitary median central incisor to cyclopia, which reflects a failure of signaling from the notochord (as discussed in Section Gene Regulatory Networks Controlled by the HH Pathway – The Glioma-Associated Transcription Factors) to instruct the midline structures (including the eye field) to expand during fetal development. Patients also exhibit neurological defects, such as agenesis of the corpus callosum, which reflects the important role of SHH during development of the brain and nervous system. IHH is known to play prominent roles during endochondral ossification of the skeleton, as shown by studies in mice, and patients with *IHH* mutations exhibit defects that reflect this function. Whereas patients with heterozygous mutations in *IHH* exhibit a reduction in the middle phalanges of their hands (known as brachydactyly type-A1, BDA1), patients with homozygous mutations have BDA1 together with a specific form of dwarfism, known as acrocapitofemoral dysplasia (ACFD), which stems from abnormal development of the appendicular skeleton. Finally, DHH is known to have much more restricted functions during embryonic development, with a restricted pattern of expression that is limited to the testis. Consistent with this, patients with *DHH* mutations only display gonadal dysgenesis.

Given that SHH, IHH, and DHH ligands all signal through the PTCH1 receptor, it comes as no surprise that patients with mutations in *PTCH1*, who have basal cell nevus syndrome (BCNS), exhibit a combination of defects that are attributable to the roles of both SHH and IHH ligands during development. These patients have skeletal defects, affecting the ribs, vertebrae and phalanges of the hands, which likely stem from defective IHH signaling. They also have polydactyly, which reflects abnormal patterning of the early limb bud by SHH (Figure 3), and abnormalities of the brain. Interestingly, whereas patients with *SHH* mutations, which render HH signaling in craniofacial structures less active, have a reduction in

midline structures (e.g., cyclopia), patients with mutations in *PTCH1*, which render HH signaling more active, have expanded midline structures (e.g., hypertelorism). Patients with mutations in *GLI2* or *GLI3* also have a similar combination of defects.

The HH pathway has also been implicated in driving several human cancers. As well as exhibiting a variety of birth defects, as described above, patients with BCNS who are heterozygous for inactivating mutations in *PTCH1* also have an increased risk for basal cell carcinomas (BCCs) and medulloblastomas (Hahn *et al.*, 1996). Given the role of *PTCH1* as a negative-regulator of the HH pathway, this finding links activated HH signaling to formation of these specific tumors which typically affect the adult skin and the brain of children, respectively. Consistent with this function of *PTCH1* as a classical tumor suppressor acting early in tumor formation, loss-of-heterozygosity at the *PTCH1* locus was reported in both familial and sporadic tumors biopsies (Gailani *et al.*, 1992). Interestingly, while germ-line *SMOH* mutations have not been reported in human birth defects (presumably because they would produce nonviable fetuses), specific somatic activating mutations in *SMOH* are found in sporadic BCCs (Lam *et al.*, 1999). Mutations in the negative-regulator *SUFU* have also been identified in these tumors type (Taylor *et al.*, 2002). Interestingly, genetic ablation of cilia in a mouse model of basal carcinoma which carries an activating mutation in *SMOH*, prevents tumors formation, thereby demonstrating the essential role of cilia in the activation of HH signaling (Wong *et al.*, 2009). Several drivers of cell proliferation and G1/S phase progression, including *C-MYC* and *CYCND1*, are positive transcriptional targets of HH signaling. Therefore, it seems logical that mutations that activate HH signaling have been described in cancer, perhaps leading to enhanced cell survival and proliferation.

Targeting the HH Pathway with Drugs

Given the importance of the HH pathway in normal development, and its deregulation in many forms of human disease, it is therefore of great clinical importance that many small molecules targeting different aspects of the pathway are available for potential treatment of disease. This area of study began over 40 years ago with the identification of cyclopamine. Epidemiologists noticed that clusters of sheep in certain mountainous areas of the United States were producing offspring with cyclopia, similar to patients with *SHH* mutations. Further investigation revealed that the source of these teratogenic effects was the Californian corn lily, which pregnant females were feeding on. These plants produce several steroidal alkaloids, including jervine and cyclopamine, which are teratogenic. A body of work subsequently showed that this compound acts as a small molecule inhibitor of SMO and thus a negative regulator of the HH pathway (Chen *et al.*, 2002). Subsequent chemical screening also identified other small molecules that target the HH pathway. Two such compounds, SAG and purmorphamine, activated HH signaling by agonizing SMO (Chen *et al.*, 2002; Sinha and Chen, 2006), suggesting that SMO is a very 'drug-gable' molecule. This is of great importance for the potential treatment of a variety of cancers caused by activation of the HH

pathway. Indeed, a next-generation orally bioavailable SMO inhibitor, GDC-0449, was used to successfully clear extensive metastatic medulloblastoma nodules in a patient with *PTCH1* loss-of-heterozygosity after only 2 months of treatment, although the metastases did relapse after 3 months, presumably owing to the acquisition of drug-resistant mutations (Rudin *et al.*, 2009). Promising results were also found in the treatment of advanced and metastatic BCC (Von Hoff *et al.*, 2009).

Interestingly, different SMO antagonists have different effects on SMO accumulation within primary cilia. For example, cyclopamine inhibits the downstream HH response, but does not prevent SMO from entering the cilium (Rohatgi *et al.*, 2009). This is analogous to the result described in *Dync2h1*^{-/-} mice, whereby SMO is constitutively localized to cilia but no HH response is elicited, showing that transport through the cilium necessary for HH signaling (Ocbina and Anderson, 2008; Ocbina *et al.*, 2011). Furthermore, constitutive localization of SMO to cilia in *Ptch1*^{-/-} cells is reversed by two other SMO antagonists, known as SANT1&2, but not by cyclopamine. These pharmacological experiments have therefore led to a model whereby SMO is regulated by trafficking to different locations within primary cilia, within which it adopts different active or inactive conformations. Clearly, the identification of pharmacological modulators of HH pathway activity will be important both for the treatment of patients with mutations in the pathway, and for dissection of the basic molecular mechanisms that regulate HH signal transduction.

Introduction

The Wnt family of secreted lipoglycoproteins constitutes one of the most fundamental signaling systems in animals, from primitive sponges to humans. Wnt proteins guide most, if not all, aspects of embryogenesis, from the early body plan to generations of various tissues and organs. In adult animals, Wnt proteins govern tissue homeostasis, including regulation of stem cell self-renewal and differentiation, and repair and regeneration upon damages and injuries (Clevers and Nusse, 2012). These various vital functions of Wnt proteins in development and homeostasis are reflected by the fact that birth defects, congenital disorders, cancers, and other diseases are frequently associated with mutations or deregulation of Wnt proteins and their downstream signaling components (MacDonald et al., 2009). Wnt proteins exert their functions through many signaling pathways, which, as a result of our incomplete understanding, are roughly classified as canonical (β -catenin-dependent) and noncanonical (β -catenin-independent) pathways. This article will focus on canonical Wnt/ β -catenin signaling, which acts through the transcriptional co-activator β -catenin to govern gene expression, and has been, relatively speaking, better defined. For noncanonical Wnt signaling pathways, which are often involved in regulation of cell polarity, movements, and possibly gene expression through various but less well characterized signaling routes, we refer readers to other excellent reviews (Wallingford, 2012; Singh and Mlodzik, 2012).

Wnt Proteins

The first Wnt gene, *Wnt1*, was initially called *int1* and discovered as an oncogene causing mouse mammary tumorigenesis (Nusse and Varmus, 1982). The famous *Drosophila* *Wingless* locus encodes a protein, Wingless (Wg), that is homologous to the Int1 protein, leading to the name Wnt (Wingless and Int) (Nusse et al., 1991). Wnt genes are found in all sequenced animal genomes. The primitive *Hydra vulgaris* has 13 Wnt genes, whereas the genome of mice or humans has 19 Wnt genes (Willert and Nusse, 2012). Wnt proteins are secreted, with an N-terminal signal peptide followed by about 350–400 amino acid residues including 22 or 24 invariable cysteines across the polypeptide forming 11 or 12 disulfide bonds (Willert and Nusse, 2012). Wnt proteins are glycosylated, but the most unusual and functionally important feature is that Wnt proteins are lipid modified (Takada et al., 2006; Willert et al., 2003). This lipid modification is referred to as O-palmitoleylation, which conjugates a monounsaturated palmitoleic acid (C16:1) onto the hydroxyl group of a conserved serine residue of the Wnt protein (Takada et al., 2006; Willert et al., 2003). Thus, Wnt proteins are hydrophobic and insoluble in water, likely accounting for the notorious

difficulty purifying Wnt proteins. Palmitoleylation likely constrains the ability of Wnt proteins to diffuse in an aqueous extracellular environment, and indeed Wnt proteins act locally in most contexts (Clevers et al., 2014). However, Wnt proteins such as Wg also act over longer distances as morphogens, which regulate cell behavior in a concentration gradient (Hausmann et al., 2007). In these instances, binding of Wnt proteins to carriers such as lipoprotein particles (Neumann et al., 2009; Panakova et al., 2005), specific partners such as Swim (Mulligan et al., 2012), and various cell surface proteoglycans such as glypicans (Filmus et al., 2008; Yan and Lin, 2009) appears to be important.

While Wg has been extensively characterized genetically, the mouse Wnt3a was the first purified, and is the best biochemically characterized, Wnt protein, in particular, in regard to palmitoleylation (Willert and Nusse, 2012; Takada et al., 2006; Willert et al., 2003). On the other hand, *Xenopus* Wnt8 was the first to be crystallized (Janda et al., 2012; Figure 1). Wnt8 structure resembles a hand with a large palm region and two finger-like (the 'thumb' and 'index finger') protrusions, which consists of looping β strands stabilized by disulfide bonds, with the most prominent feature being the palmitoleate adduct at the tip of the Wnt8 thumb pointing outwards (Figure 1). Based on the Wnt structure and bioinformatics, it has been speculated that the primordial Wnt protein is evolved from an ancient fusion of a saposin-like and a cytokine-like domains (Bazan et al., 2012). Thus Wnt lipid

Figure 1 Structure of xWnt8. Surface representation and secondary structure of xWnt8 (magenta) as viewed 'face on.' The two N-Linked glycans of xWnt8 (N104 and N263) are drawn in green shapes. The palmitoleic acid (PAM) group is shown in red extending from the Wnt thumb. Disulfide bonds are shown in black. NTD and CTD, N- and C-terminal domains. This structure was generated using PyMOL software and the crystal structure of xWnt8 published by Janda et al. (2012).

modification is a cardinal feature that has profound effects on Wnt proteins, from secretion to signaling (see below).

Wnt Protein Biogenesis

The unusual properties of Wnt proteins, particularly palmitoleoylation, imply the existence of unique machineries for their biogenesis and secretion. Indeed, genetic screens in *Drosophila* and nematodes have identified a number of genes that have conserved functions in Wnt biogenesis and secretion from invertebrates to mammals (Willert and Nusse, 2012; Hausmann *et al.*, 2007; Figure 2). Porcupine (Porc) is a multi-span transmembrane protein residing in the endoplasmic reticulum (ER) and is likely a Wnt-specific O-acyltransferase responsible for Wnt palmitoleoylation. The p24 family of transmembrane cargo receptors, which are known to be involved in ER exit of glycosylphosphatidylinositol (GPI)-anchored proteins, are required for Wnt exit from the ER to Golgi. Wntless (Wls), also known as Evenness interrupted or Sprinter or Gpr177, is a multi-span transmembrane protein that binds to palmitoleoylated Wnt proteins in the Golgi, chaperoning them through the exocytic pathway to the plasma membrane (PM) for release. The critical importance of Wls in Wnt secretion is reflected in findings that Wls recycling from the PM to Golgi is critical. Thus the retromer complex, sorting nexin-3 (SNX3), and the MTM-6/MTM-9 myotubularin proteins that are lipid phosphatases for phosphatidylinositol-3-phosphate (PI3P), are each required for retrieval of Wls from the PM back to Golgi for Wnt secretion. Studies in mammalian cells have implicated stearoyl desaturase (SCD) and the V-ATPase in Wnt biogenesis: SCD converts abundant palmitic acid into palmitoleic acid for adduction into Wnt by Porc (Rios-Esteves and

Resh, 2013), whereas the V-ATPase, a proton pump for vesicular acidification, appears to be required for release of Wnt from Wls at the PM. In this sophisticated Wnt production cascade (Figure 2), Porc and Wls appear to be dedicated to Wnt biogenesis while the other proteins/complexes likely have additional functions in vesicular trafficking or lipid metabolism, although the loss of function of these genes commonly produces loss of Wnt phenotypes (a consequence of prominent influence of Wnt signaling on embryogenesis).

Wnt Receptors: Frizzled and LRP5/6

Several families of Wnt receptors have been described. For canonical Wnt/ β -catenin signaling, the Frizzled (Fz) family of serpentine receptors and LDL receptor-related proteins 5 and 6 (LRP5/6) are both essential and will be reviewed in detail here. Other Wnt receptors such as Ryk, Ror, and Ptk7, which belong to the atypical receptor tyrosine kinase (RTK) family, have primary roles, either alone or together with Fz, in non-canonical Wnt signaling, on which we refer readers to some excellent reviews (Green *et al.*, 2014; Peradziriyi *et al.*, 2012).

Fz receptors harbor an extracellular cysteine-rich domain (CRD) that binds to Wnt proteins with high affinities (1–10 nM), and participate in perhaps most, if not all, Wnt pathways (Figure 3; MacDonald and He, 2012). How a Wnt ligand engages Fz is illustrated by the xWnt8–Fz8CRD co-crystal structure (Janda *et al.*, 2012; Figure 3). In the complex, the xWnt8 thumb interacts with Fz8CRD through hydrophobic contacts and inserts the palmitoleoylate adduct into a hydrophobic cleft of Fz8CRD in a ‘lipid in groove’ fashion (site 1), while the xWnt8 index finger ends in a vicinal disulfide bond that wraps around the other edge of Fz8CRD through

Figure 2 Wnt protein biogenesis. Glycosylation and lipidation of Wnt occur in the endoplasmic reticulum (ER) and require porcupine. P24 is required for Wnt export from the ER. Wnt proteins are transported by Wntless from the Golgi to the PM. Wntless is recycled from endocytic vesicles back to the golgi by the retromer complex formed by SNX3 and the myotubularins proteins. After secretion, mature Wnt can bind to glypicans, travel on lipoprotein particles or form aggregates.

Figure 3 Wnt receptors: Frizzled and LRP6 (a) representation of Frizzled (Fz) and LRP6. LRP6 binding to different Wnt proteins and antagonists SOST and DKK1 are shown. CRD (cysteine-rich domain), E1–E4 (EGF-repeats), P1–P4 (β -propeller domains) (b) xWnt8–Fz8CRD co-crystal structure, shown as a ribbon diagram superimposed on surface representation (Janda *et al.*, 2012). (c) Side and top views of the secondary structure of LRP6 P3E3–P4E4 (Chen *et al.*, 2011).

hydrophobic contacts, ‘knob-in-hole’ fashion (site 2) (Figure 3; Janda *et al.*, 2012). Thus, xWnt8 resembles a human hand with a central palm that extends the thumb and the index finger to grab/pinch Fz8CRD (Figure 3). Because contact residues of Wnt and Fz proteins at site 1 and site 2 are conserved but with variations, the relative broad specificity of Wnt–Fz binding, i.e., one Wnt binding to multiple Fz proteins and vice versa, can be rationalized by this unusual ligand–receptor structure, in which Wnt palmitoleoylation has a critical role.

LRP5 and LRP6 (and their *Drosophila* homolog Arrow) are single-span transmembrane proteins and act as essential coreceptors for Fz in Wnt/ β -catenin signaling, but unlike Fz, they are not required for noncanonical Wnt pathways (MacDonald and He, 2012; He *et al.*, 2004). LRP5 and LRP6 share partially redundant functions, with LRP6 being a more dominant of the two, during mouse embryogenesis (He *et al.*, 2004). However, LRP5 is critical for human bone mass accrual and is thus a key player in osteoporosis pathogenesis (Regard *et al.*, 2012). The ectodomain of LRP5 and LRP6 are composed of four repeating units, P1E1 to P4E4, each of which is a so-called YWTD- β -propeller domain (P) juxtaposed by an EGF-repeat (E), followed by three LDL receptor type A (LDLR-A) repeats before the transmembrane domain (Figure 3; MacDonald and He, 2012; He *et al.*, 2004). Wnt proteins promote Fz–LRP6

complex formation *in vitro*, and therefore bind to Fz and LRP6 simultaneously (Tamai *et al.*, 2000; Bourhis *et al.*, 2010). The PE domains are involved in Wnt-binding, and interestingly, P1E1 and P3E3 appear to bind different sets of Wnt ligands, with Kd values at about 10 nM (Ahn *et al.*, 2011; Chen *et al.*, 2011). Structural studies suggest that the top surface of the YWTD- β -propeller domains, P1 and P3, are likely the binding sites for Wnt proteins (Ahn *et al.*, 2011; Chen *et al.*, 2011), although a lack of a Wnt–LRP5/6 co-crystal structure prohibits a definitive assignment. P2E2 and P4E4 are essential for the structural integrity of the PE units (Bourhis *et al.*, 2010; Liu *et al.*, 2009), but it is unknown whether they bind Wnt or other ligands (see below). The role of LDLR-A repeats is less clear, although their involvement in LRP5/6 dimerization has been suggested (Ahn *et al.*, 2011). The intracellular domain of LRP5/6 (and Arrow) is conserved with multiple phosphorylation motifs that are essential for Wnt/ β -catenin signaling activation (see below).

Wnt Antagonists

Many families of secreted or membrane-bound antagonists of Wnt signaling have been identified, and they expand strategies

Figure 4 Wnt/ β -catenin signaling modulators. (a) Secreted inhibitors such as DKK1 and SOST prevent canonical signaling through negative actions on LRP5/6. SFRPs and WIF inhibit Wnt signaling by direct binding to Wnt ligands. Membrane tethered Tiki and Notum (depicted as a fly) inactivate Wnt by cleaving the N-terminal or deacylating Wnt respectively. Ubiquitin ligases Rnf43 and Znf3 promote LRP5/6 and Frizzled receptors turnover. (b) R-spondin proteins act as potent enhancers of Wnt signaling by clearing Rnf43 and Znf3 inhibitors from the plasma membrane. Norrin and TSPAN12 enhance Wnt signaling by promoting Fz4 and LRP5/6 clustering.

of Wnt signaling regulation far beyond an already complex Wnt-receptor network (Cruciat and Niehrs, 2013; Malinauskas and Jones 2014). These factors can be classified based on their mechanisms of actions (Figure 4(a)). Secreted Frizzled-related proteins (sFRPs) share homology with the Fz CRD, and bind and titrate Wnt from Fz (and may also heterodimerize with Fz); sFRPs may have biphasic functions and can enhance the range of Wnt proteins presumably by shielding the lipid moiety to facilitate Wnt diffusion (Mii and Taira, 2009). Other Wnt-binding antagonists include Wnt inhibitory factor (WIF) and *Xenopus* Cerberus (Cruciat and Niehrs, 2013). Dickkopf-1 (Dkk1) on the other hand binds to LRP5/6 with high affinity and competes with Wnt for the coreceptors; Wise and SOST, which is a human skeletal disease gene product, act in a similar manner. However, Dkk1 binds to P1E1 and P3E3 of LRP6 whereas SOST binds to P1E1, thereby exhibiting inhibition toward different Wnt proteins (Ahn et al., 2011; Chen et al., 2011; Bourhis et al., 2011). Fz is also a key regulatory target. Shisa is an ER-resident protein that traps Fz (and also the fibroblast growth factor receptor, FGFR) in the ER to prevent Wnt signaling, whereas RNF43 and ZNRF3 are homologous transmembrane proteins with an intracellular E3 ligase domain that ubiquitinate Fz, thereby triggering degradation of Fz and associated coreceptors including LRP6 (Furushima et al., 2007; Yamamoto et al., 2005; Koo et al., 2012; Hao et al., 2012) (also see below). More recently Wnt modifying and inactivating enzymes have been identified. Tiki1 and Tiki2 are membrane-anchored metalloproteases that cleave the N-terminus of some Wnt proteins, whereas Notum is a Wnt deacylase that removes the palmitoleoylate adduct, with both types of enzymes fully inactivating Wnt ligands (Zhang et al., 2012, 2015; Kakugawa et al., 2015). There are several additional Wnt antagonists that share mechanisms similar to those mentioned (Cruciat and Niehrs, 2013; Malinauskas and Jones, 2014).

Wnt Agonists

Norrin (Norrie Disease gene product) and R-spondin (Rspo) proteins are two families of secreted Wnt agonists (Figure 4 (b)). Norrin binds to Fz4 (but not any other Fz) and LRP5/6 (Wang et al., 2012; Ke et al., 2013) and thus acts in a manner analogous to Wnt proteins but with a strict Fz4 choice. Norrin (but not Wnt) shows dependence on a tetraspannin protein, TSPAN12, which appears to promote Fz4 clustering (Junge et al., 2009). On the other hand, Rspo proteins act primarily as enhancers of Wnt signaling in a sophisticated fashion. Rspo binds to two types of cell surface receptors: leucine-rich repeat containing G-protein-coupled receptors 4/5/6, LGR4/5/6, which like Fz are serpentine receptors, and the aforementioned RNF43/ZNRF3 ubiquitin ligases (Malinauskas and Jones, 2014; de Lau et al., 2014). The Rspo-LGR-RNF43/ZNRF3 trimeric complex promotes the removal of RNF43/ZNRF3 from the PM, preventing RNF43/ZNRF3 from degrading Fz and LRP6 (Malinauskas and Jones, 2014; de Lau et al., 2014). Thus, Rspo stabilizes Fz and LRP6 on the cell surface for Wnt signaling. LGR5 is an intestinal stem cell marker, and Rspo and Wnt proteins are key stem cell growth/self-renewal factors (de Lau et al., 2014).

The ‘Wnt-Off’ State: Keeping β -Catenin Levels Low

β -Catenin has two different roles in animal cells: it is an essential transcriptional co-activator in the Wnt pathway (as covered in this article), and it is also a critical component of the E-cadherin- β -catenin adherens junction at the PM (Valenta et al., 2012). Although only the cytoplasmic pool of β -catenin is under Wnt control, the junctional pool of β -catenin may crosstalk with the Wnt pathway in manners that remain to be understood.

Wnt regulation of β -catenin can be best described in a 'two-state' model (Clevers and Nusse, 2012; MacDonald *et al.*, 2009). In the 'Wnt-off' state, cytoplasmic β -catenin levels are kept low thanks to the so-called 'destruction complex,' whose main mission is to destruct β -catenin (Stamos and Weis, 2013). This multi-protein complex is assembled by the scaffolding protein Axin, and contains two kinases, casein kinase 1 α (CK1 α) and glycogen synthase kinase 3 (GSK3 α or GSK3 β), in addition to the APC (adenomatous polyposis coli) tumor suppressor/scaffolding protein and β -catenin (Figure 5). Axin is the ringleader and binds directly to each of the above core components, with help of additional interactions such as be-

Figure 5 β -Catenin destruction complex. In absence of Wnt, Axin forms a complex with CK1 α , GSK3, APC, and β -catenin. CK1 α and GSK3 sequentially phosphorylate β -catenin, which creates a recognition motif for β -TrCP, thereby coupling β -catenin phosphorylation to its ubiquitination and degradation by the proteasome. In addition, phosphorylation of Axin by CK1 α , GSK3 promote Axin to adopt an 'open' conformation critical for the destruction complex assembly. Protein phosphatases 1 and 2A act to counter CK1 α and GSK3 actions.

tween APC and β -catenin (Figure 6). CK1 α and GSK3 are the executioners of the complex by sequentially phosphorylating β -catenin. Thus phosphorylation of S45 by CK1 α primes that of T41, S37, and S33 by GSK3; phosphorylation of S37 and S33 of β -catenin creates a recognition motif for binding by β -TrCP, a subunit of an E3 ubiquitin ligase complex, thereby coupling β -catenin phosphorylation to its ubiquitination and degradation by the proteasome. The destruction complex deconstructs β -catenin through phosphorylation-ubiquitination in a cyclic fashion.

Axin has a 'DIX' domain (Figure 6), which is also found in Disheveled (Dvl) (see below) and has the ability to polymerize (Schwarz-Romond *et al.*, 2007). Such DIX-mediated oligomerization of Axin is suggested to be a key feature of the destruction complex assembly, which has been referred to as the 'degradosome.' Although β -catenin phosphorylation by CK1 α and GSK3 is the central task of the destruction complex, Axin and APC themselves are substrates of CK1 α and GSK3, and their phosphorylation appear to be critical for the destruction complex assembly. Phosphorylation of Axin and APC enhances their binding to, and thus capture of, β -catenin (Willert *et al.*, 1999a; Spink *et al.*, 2000; Xing *et al.*, 2003), thereby facilitating destruction of β -catenin. In the case of Axin, this seems to be a result of phosphorylation-regulated conformational changes: phosphorylation by GSK3 (and likely CK1 α) promotes Axin to adopt an 'open' conformation that is conducive to its scaffolding function (Kim *et al.*, 2013b; Figure 5). Indeed protein phosphatases (PPs), which are also components of the destruction complex, act to counter CK1 α and GSK3 in multiple ways. PP1 dephosphorylates Axin to promote a 'closed' conformation through Axin intramolecular interaction/autoinhibition (Kim *et al.*, 2013b), whereas PP2A dephosphorylates β -catenin and prevents it from recognition- and ubiquitination by β -TrCP (Ikeda *et al.*, 2000; Seeling *et al.*, 1999; Figure 5). Therefore the destruction complex is an oiled machinery with accelerators (kinases) and brakes (phosphatases).

APC is a tumor suppressor in the gastrointestinal tract and its loss of function mutations are found in about 80% of

Figure 6 Hallmarks of Dvl, Axin1, and APC proteins. (A) Shows Dvl N-terminal DIX domain involved in oligomerization, PDZ and DEP domains. (B) Axin features a RGS domain, GSK3-binding domain (GBD), β -catenin-binding domain (BCD), and also a C-terminal DIX domain. (C) *Wt* APC has an oligomerization domain, followed by the Arm repeats, 15 and 20 a.a. repeats mediating β -catenin binding, SAMP motifs mediating Axin binding, a basic domain, EB1 and PDZ domains. APC nuclear localization sequences (NLS) and nuclear export sequences (NES) are also shown.

colorectal cancer cases (Polakis, 2012). But the biochemical nature of the APC protein in the destruction complex remains debated, with several (but not mutually exclusive) functions proposed in various models. These include assembly of the destruction complex, dynamic assembly and disassembly of the complex, inhibition of dephosphorylation of β -catenin, a requirement in both phosphorylation and ubiquitination of β -catenin, oligomerization, and cytoplasmic retention of β -catenin (Stamos and Weis, 2013). Another prominent but enigmatic component of the destruction complex is WTX (Wilms tumor gene on X) or Amer1, another tumor suppressor protein that is vertebrate-specific and required for β -catenin degradation (Regimbald-Dumas and He, 2011; Tanneberger et al., 2011).

Given the central role of Axin in the assembly of the destruction complex, regulation of Axin protein abundance/stability has attracted significant attention. Tankyrases (TNKS1 and TNKS2) promote Axin ubiquitination and proteasomal degradation through PARsylation of Axin (Zhang et al., 2011b; Huang et al., 2009). As such, small molecule inhibitors of TNKS have been identified that elevate Axin protein levels and thus decrease β -catenin protein amounts (Huang et al., 2009; Chen et al., 2009), highlighting a potential therapeutic strategy for inhibition of β -catenin signaling in cancer. However, TNKS does not appear to be under Wnt regulation.

The 'Wnt-On' State: Raising β -Catenin Levels High

Formation of the Wnt-receptor signaling complex/signalosome

Wnt binds to Fz and LRP6 and promotes Fz–LRP6 complex formation, triggering stabilization and accumulation of β -catenin (MacDonald and He, 2012; He et al., 2004). A hallmark of the receptor activation is Wnt-induced LRP6 phosphorylation on its five conserved PPPSPxS motifs and a few additional S/T residues outside these motifs (MacDonald and He, 2012). Dually phosphorylated PPPSPxS motifs are key signaling modules of LRP6 by serving as docking sites for Axin, thereby promoting the recruitment of the Axin destruction complex by the activated Wnt receptor complex. How Axin binds to phosphorylated LRP6 has not been resolved, with data and models supporting a direct (MacDonald et al., 2011) or indirect (Piao et al., 2008; Stamos et al., 2014) interaction.

A phosphorylated PPPSPxS motif under experimental conditions is sufficient to activate β -catenin signaling (Tamai et al., 2004), suggesting that LRP6 phosphorylation is the critical output of the Wnt receptor complex. Paradoxically, the kinases responsible for phosphorylation of the PPPSPxS motifs are GSK3 (on PPPSP) and CK1 (on xS) (MacDonald and He, 2012). In fact, GSK3 in complex with Axin carries out LRP6 phosphorylation (Zeng et al., 2008; Figure 7). Thus GSK3 and Axin, both of which have negative roles in Wnt signaling through promoting β -catenin phosphorylation and degradation, also have positive roles in Wnt signaling via promoting LRP6 phosphorylation, and these opposing roles of GSK3 in Wnt signaling have been experimentally demonstrated (Zeng et al., 2008, 2005). Multiple CK1 isoforms, including CK1 α , CK1 ϵ , and CK1 γ , may have roles in LRP6

Figure 7 Wnt receptor activation. In the presence of Wnt ligand, a receptor complex forms between Fz and LRP6. Dvl interaction with Fz leads to Axin-GSK3 recruitment and phosphorylation of the PPPSP motif of LRP6 which primes xS phosphorylation by CK1, probably via CK1 γ (membrane-associated) and/or CK1 α and CK1 ϵ associated with Axin and Dvl. Partially phosphorylated LRP6 may be able to recruit and more efficiently bind Axin-GSK3 and promote more PPPSPxS phosphorylation.

phosphorylation (MacDonald and He, 2012). Additional kinases have been suggested to participate in LRP6 phosphorylation (MacDonald and He, 2012). Given its importance, most receptor proximal components are involved in controlling LRP6 phosphorylation, including Fz, the Fz cytoplasmic partner Dvl, and a number of Dvl-interacting proteins (MacDonald and He, 2012; Figure 7).

Dvl is an enigmatic scaffolding protein (Figure 6) and acts downstream of Fz, likely through direct Fz–Dvl binding (Tauriello et al., 2012; Wong et al., 2003). Unlike LRP5/6, which are specifically required for the Wnt/ β -catenin pathway, the Fz/Dvl pair is required for most, if not all, Wnt pathways (van Amerongen, 2012; Gao and Chen, 2010). Both Fz and Dvl functions are essential for Wnt-induced LRP6 phosphorylation, which depends on Fz–LRP6 proximity and Fz–Dvl interaction (Zeng et al., 2008). Like Axin, Dvl has a DIX domain (Figure 6) that mediates polymerization, as either homotypic Dvl assemblies or heterotypic Dvl–Axin assemblies (Schwarz-Romond et al., 2007). Dvl–Axin interaction appears to be critical for recruiting the Axin–GSK3 complex by Fz–Dvl into the Wnt receptor complex for phosphorylation of the PPPSP motif of LRP6 (Figure 7), which primes xS phosphorylation by CK1 (Zeng et al., 2008, 2005). Note that the phosphorylated PPPSPxS motif recruits Axin, which promotes PPPSPxS phosphorylation, creating a positive feed forward loop for Axin recruitment and LRP6 phosphorylation and supporting a Fz–LRP6 signaling ‘initiation–amplification’ model (MacDonald et al., 2008; Baig-Lewis et al., 2007). A related ‘LRP6 signalosome’ model, which posits LRP6 aggregation that depends on the property of Dvl polymerization and recruitment of Axin, has also been proposed (Schwarz-Romond et al., 2007; Bilic et al., 2007).

Several additional notable players have also been suggested to participate in LRP6 phosphorylation. Although a contentious subject, evidence exists to argue for a role of trimeric G-protein acting downstream of the Fz serpentine receptor (Katanaev *et al.*, 2005). A study suggests that the $G\beta\gamma$ subunits are associated with the LRP6 signaling complex including Dvl and Axin and recruit GSK3 to phosphorylate LRP6 (Jernigan *et al.*, 2010). Dvl is also associated with PI4K and PIP5K, two lipid kinases that stimulate PIP2 production to promote LRP6 phosphorylation (Pan *et al.*, 2008). PIP2 appears to enhance LRP6 aggregation or signalosome formation (Kim *et al.*, 2013a) and/or recruit WTX/Amer1, which in turn recruits Axin–GSK3 for LRP6 phosphorylation (Tanneberger *et al.*, 2011). These studies point to a multivalent assembly of the Fz–Dvl–LRP6–Axin signaling complex/signalosome, promoted by, and promoting, LRP6 phosphorylation.

β -Catenin Stabilization

How the Wnt receptor signaling complex/signalosome formation leads to β -catenin stabilization has been a contentious subject. A number of models have been proposed and reviewed (MacDonald and He, 2012), and we discuss four main and more recent models. An important consideration is β -catenin stabilization kinetics, which shows a rapid accumulation phase and a subsequent plateau phase upon Wnt treatment in mammalian cells (Kim *et al.*, 2013b; Hernandez *et al.*, 2012). This kinetics can be best explained in the following way: without Wnt, the rate of β -catenin protein synthesis equals that of its degradation (by the destruction complex), representing a steady state of no β -catenin accumulation; with Wnt, the rate of β -catenin degradation is slowed down and becomes less than that of β -catenin protein synthesis, leading to β -catenin accumulation until the level plateaus; this plateau represents a new steady state where the rate of β -catenin protein synthesis equals that of its degradation again, suggesting that the β -catenin destruction complex is fully operational at this steady state (in the presence of Wnt). A mechanistic model of β -catenin stabilization needs to account for this simple (but often underappreciated) kinetics.

A model of ‘Direct inhibition of GSK3 by LRP6’ (Figure 8(a)) was proposed based primarily on reconstitution *in vitro* (Piao *et al.*, 2008; Wu *et al.*, 2009; Cselenyi *et al.*, 2008). This model posits that LRP6 directly binds to GSK3 through phosphorylated PPPSPxS motifs and inhibits its phosphorylation of β -catenin, thereby stabilizing β -catenin. Within the LRP6 signaling complex/signalosome LRP6 and GSK3 are in proximity, and there is some evidence that a phosphorylated PPPSPxS motif binds to the catalytic cleft of GSK3 (Stamos *et al.*, 2014). However, it is unclear whether this binding represents GSK3–substrate or GSK3–inhibitor interaction. A related uncertainty remains whether LRP6 binds directly to Axin or GSK3 or both simultaneously. This static model has stringent requirements for the relative abundance of activated/phosphorylated LRP6 versus Axin and/or GSK3 in the cytoplasm.

A model of ‘MVB (multivesicular body) sequestration of GSK3’ suggests that after LRP6 signaling complex/signalosome formation, endocytosis of this complex leads to wrapping and thus sequestration of associated GSK3 into MVBs, thereby

separating GSK3 from β -catenin by two layers of membranes (Figure 8(b); Taelman *et al.*, 2010). Because GSK3 protein levels do not change during Wnt signaling, this model does not explain how GSK3 escapes MVBs, which normally destine cargos for lysosomal degradation. This model also requires that LRP6 recruits most or all GSK3 for sequestration, a challenging task if GSK3 is more abundant than LRP6. An important feature of this model is the ‘spillover’ effect in which Wnt signaling would inhibit most or all GSK3-mediated phosphorylation events.

While the prevailing view is that inhibition of β -catenin phosphorylation prevents β -catenin binding, and thus ubiquitination, by β -TrCP, a model of ‘Axin complex saturation’ argues that Wnt inhibits β -catenin binding and ubiquitination by β -TrCP without affecting β -catenin phosphorylation (Li *et al.*, 2012). In this scenario, phosphorylated but un-ubiquitinated and un-degraded β -catenin would remain in and saturate the Axin complex (that has been recruited to phosphorylated LRP6), thereby preventing the newly synthesized β -catenin from entering the destruction complex (Figure 8(c)). This model does not explain why phosphorylated β -catenin ‘prevents’ un-phosphorylated β -catenin from binding to the Axin complex based on protein thermodynamics and why phosphorylated β -catenin cannot be recognized by β -TrCP.

A more recent model is ‘Axin inactivation,’ which is based on the idea that phosphorylation regulates Axin intramolecular interaction and therefore its scaffolding function and destruction complex assembly (Kim *et al.*, 2013b; Figure 8(d)). Axin phosphorylation by GSK3 inhibits the intramolecular interaction, thereby keeping Axin in an active and ‘open’ conformation for β -catenin binding and poised for phosphorylated LRP6 binding; Axin dephosphorylation by PP1 promotes the intramolecular interaction, thereby rendering Axin in an inactive and ‘closed’ conformation that binds to neither β -catenin nor phosphorylated LRP6. Wnt signaling promotes Axin dephosphorylation and inactivation (Willert *et al.*, 1999a,b; Kim *et al.*, 2013b; Luo *et al.*, 2007). This model suggests that phosphorylated LRP6 binds to and recruits only active and phosphorylated Axin for inactivation in a cyclic manner. Further, this model posits that rising β -catenin levels upon Wnt signaling compete with and inhibit Axin intramolecular interaction, thereby promoting reassembly of the Axin destruction complex and potentially accounting for the steady state/plateau of β -catenin accumulation. Of the four models discussed here, the Axin inactivation model permits β -catenin stabilization regardless of relative abundance of LRP6 versus Axin, and is sufficient to explain β -catenin stabilization kinetics.

Wnt Signaling in the Nucleus

Nucleus Import

β -Catenin can shuttle between cytoplasm and nucleus. A classic nuclear protein contains a nuclear localization sequence (NLS), which strongly binds nuclear pore protein, importin/karyopherin. With the assistance of Ran GTPase, the cargo is moved through the nuclear envelop and released in the nucleus. However, β -catenin does not have a NLS. It has been found that β -catenin can enter nucleus in Ran-independent manner

Figure 8 β -Catenin stabilization models. (a) In this model LRP6 directly binds to GSK3 through phosphorylated PPPSPxS motifs and inhibits phosphorylation of β -catenin, thereby stabilizing β -catenin. (b) Another model suggests that after LRP6 signaling complex/signalsome formation, endocytosis of this complex leads to wrapping and sequestration of associated GSK3 into multivesicular bodies. (c) In this view, Wnt inhibits β -catenin binding and ubiquitination by β -TrCP without affecting β -catenin phosphorylation. (d) This model suggests that Axin phosphorylation by GSK3 inhibits the intramolecular interaction, thereby keeping Axin in an active and 'open' conformation for β -catenin binding and poised for phosphorylated LRP6 binding; Axin dephosphorylation by PP1 promotes the intramolecular interaction, thereby rendering Axin in an inactive and 'closed' conformation that binds to neither β -catenin nor phosphorylated LRP6.

(Yokoya *et al.*, 1999). Since β -catenin and importin share similar armadillo-repeat domains, β -catenin might directly interact with nuclear pore components, bypassing the importin/karyopherin proteins (Yokoya *et al.*, 1999; Fagotto *et al.*, 1998). β -Catenin nuclear localization is regulated by phosphorylation. Protein kinase AKT can phosphorylate β -catenin at Ser552 and promote β -catenin nuclear localization (Fang *et al.*, 2007; He *et al.*, 2007). In response to Rac1 activation, JNK2 also phosphorylates β -catenin at Ser191 and Ser605 and regulate nuclear translocation of β -catenin (Wu *et al.*, 2008). In glioma cells, FoxM1, a forkhead box transcription factor, interacts with β -catenin and promotes its nuclear translocation (Zhang *et al.*, 2011a). Whether FoxM1 controls β -catenin nuclear localization in normal cells is not known.

Nuclear Export

β -Catenin can be shuttled in and out of the nucleus in response to Wnt signaling. β -Catenin does not contain a classical nuclear

export sequence (NES). β -Catenin nuclear export is controlled by other proteins in the Wnt pathway, such as Axin (Cong and Varmus, 2004) and APC (Rosin-Arbesfeld *et al.*, 2000; Henderson, 2000; Neufeld *et al.*, 2000). These components in the β -catenin destruction complex also participate in nuclear export of β -catenin. APC contains several NES sequences, which bind exportin, another member of the karyoporin family (f. Binding of Ran-GTP to exportin enhances its affinity to NES and promotes the export of exportin and its cargo through nuclear pore. Ran GTPase releases the cargo and recycles exportin to the nucleus by converting Ran-GTP to Ran-GDP. APC may act as a shuttle for β -catenin nuclear export. Some factors may not directly participate in shuttling, but rather as an 'anchor' to retain β -catenin within their respective compartments (Krieghoff *et al.*, 2006). The nuclear proteins described below, such as TCF-4, Pygopus, and BCL9 may function as nuclear 'anchors' (Townesley *et al.*, 2004). E-Cadherin function as a membrane 'anchor' and Axin may function as a cytoplasmic 'anchor' of β -catenin (Tolwinski and Wieschaus, 2001).

β -Catenin/TCF Complex

β -Catenin is a transcription co-activator that interacts with TCF/LEF (T-cell factor/lymphoid enhancer-binding factor) family of transcription factors in the nucleus (MacDonald *et al.*, 2009). The TCF/LEF factors are high-mobility group (HMG) DNA-binding proteins. There is only one TCF gene in *Drosophila* and worm. In mammalian cells, the TCF/LEF family includes TCF1 (TCF7 by HUGO), LEF-1, TCF-3 (TCF7L1), and TCF-4 (TCF7L2). Alternative promoters and splicing further expand the variety of TCF/LEF isoforms generating context dependent patterns of activity. The N-terminus of TCF/LEF binds β -catenin and the HMG domain binds a specific DNA sequence called Wnt responsive elements (WRE). The consensus WRE sequence is: CCTTTGNN (N represents either T or A). The TCF in invertebrates and some spliced form of TCF/LEF proteins in vertebrates have a second highly conserved DNA-binding domain referred to as 'C Clamp,' which binds to GC-rich sequences referred to as 'helper sites' that are found in proximity to some WREs (Figure 9(a); Bhambhani *et al.*, 2014; Hoverter *et al.*, 2014). Some alternative splicing products of TCF/LEF lack the C Clamp or other regions in N-terminal of the HMG domain (Van de Wetering *et al.*, 1996; Prokunina-Olsson *et al.*, 2009). Many Wnt target genes contain

Figure 9 β -Catenin/TCF complex. (a) Hallmarks of β -catenin and TCF/LEF proteins. β -Catenin has a β -TrCP-binding motif in N-terminal, 12 armadillo repeats and a transactivation domain. TCF/LEF proteins have a β -catenin-binding domain (BD), a groucho-binding site (GBS) followed by the high-mobility group (HMG), a basic tail or NLS and a C clamp domain. (b) In absence of Wnt, target genes are constitutively inhibited by nuclear TCF in complex with corepressors such as CtBP, HDAC1, HDAC2, and groucho/TLE on Wnt response elements (WREs). (c) In presence of Wnt, β -catenin translocates to the nucleus, where it displaces TCF-bound corepressors or co-imports additional TCF to occupy WREs. Once bound, β -catenin functions as a scaffold to recruit co-activators involved in chromatin remodeling such as histone acetyltransferases CBP and P300 and histone methyltransferases MLL1-2, WDR5, RbBP5 and SET8, and components of the PAF1 complex itself interacting with RNA polymerase II to induce Wnt target gene expression.

multiple WRE sequences in the promoter region or distant sites (Hatzis *et al.*, 2008). Different sets of target genes are regulated by WREs with or without helper sites, suggesting an additional layer of regulation in *Drosophila* embryos and mammalian cells (Bhambhani *et al.*, 2014; Hoverter *et al.*, 2014).

TCF/LEF factors act as both transcription activators and repressors depending on the status of Wnt signaling. Without Wnt stimulation, TCF/LEF factors recruit corepressors such as CtBP, HDAC1, MTGR1, Coop, HIC5, and the most studied Groucho/TLE to inhibit transcription (Figure 9(b); MacDonald *et al.*, 2009; Cadigan and Waterman, 2012). In response to Wnt signaling, β -catenin is stabilized in the cytoplasm and enters nucleus, where it binds TCF/LEF, displaces Groucho/TLE from TCF/LEF and activates transcription by recruiting other co-activators (Figure 9(c)). Recently, it was found that the N-terminal domain of the Groucho/TLE1 forms a tetramer that specifically binds to K20 methylated Histone H4 tail (Chodaparambil *et al.*, 2014). Some factors regulate this competition between β -catenin and Groucho/TLE1 for TCF/LEF binding. In zebrafish the transcription factor Ladybird homeobox 2 (Lbx2) enhances Wnt/ β -catenin signaling pathway in the posterior lateral and ventral mesoderm during gastrulation, by directly interfering with Groucho/TLE binding to TCF (Lu *et al.*, 2014). This TCF/LEF transcriptional switch model is supported by observations in *Drosophila* and *Caenorhabditis elegans*. However, in vertebrates individual TCF/LEF have distinct ability to activate or repress Wnt target gene expression with TCF-3 generally known as a repressor and TCF1 and LEF-1 more often associated with gene activation (MacDonald *et al.*, 2009; Cadigan and Waterman, 2012). In addition, the switch between active and recessive forms of TCF/LEF could be mediated by factors other than the direct competition between β -catenin and Groucho/TLE1 for TCF/LEF binding. For instance, in *Xenopus* Wnt promotes the phosphorylation of the repressor TCF-3 by HIPK2, which lead to its dissociation, and replacement by TCF1 from *Vent2* gene WRE (Hikasa *et al.*, 2010).

Co-Activators

β -Catenin has multiple and extensive protein-protein interaction domains. The N-terminus contains the destructing box that upon phosphorylation binds β -TrCP. The C-terminus contains a transactivation domain, which binds histone acetyltransferase (HAT) CBP/p300 (MacDonald *et al.*, 2009; Cadigan and Waterman, 2012). The armadillo-repeat domain in the middle of β -catenin binds E-cadherin on the PM and Axin and APC in the cytoplasm and nucleus. In addition, the N-terminal armadillo repeats interact with transcription co-activators, BCL9/Legless and Pygopus (Figure 9(c); MacDonald *et al.*, 2009; Cadigan and Waterman, 2012).

HATs

Histone modification is required for Wnt-mediated transcription. CBP and p300 are HATs that acetylate lysines on histones. This modification is essential to reduce the overall positive charge and to loosen chromatin at Wnt target genes, in order to facilitate binding of transcription factors and activate transcription (Ogryzko *et al.*, 1996; Goldman *et al.*, 1997).

HATs also acetylate β -catenin and TCF and regulate the activity of the TCF complex (Levy *et al.*, 2004). Recently, Walker *et al.* (2015) showed that FOXP1 promotes acetylation of β -catenin by CBP and potentiation of β -catenin-dependent transcription. Histone deacetylases (HDACs) have opposite roles as HATs. It has been found that HDAC1 and HDAC2 disrupt the β -catenin/TCF complex and inhibit Wnt signaling (Figure 9(b); Ye *et al.*, 2009). Corepressor Groucho/TLE may maintain a repressive chromatin environment by interacting with hypoacetylated histone H3 (Palaparti *et al.*, 1997). However, there are four classes of HDACs. HDAC1 and HDAC2 belong to class I HDACs (Barneda-Zahonero and Parra, 2012). Whether other HDACs have roles in Wnt signaling is unclear.

Histone Methyltransferases

Histone methyltransferases (HMTs) are also involved in Wnt target gene activation. It has been reported that β -catenin interacts with Ash2L, a member of the Set1/MLL HMT complexes (Sierra *et al.*, 2006). There are six members of Set1/MLL HMTs; Ash2L, along with WDR5 and RbBP5 are shared subunits of these Set1/MLL complexes (Krivtsov and Armstrong, 2007). The Set1/MLL complexes catalyze Histone 3 lysine 4 trimethylation (H3K4Me3), which is generally required for gene expression including Wnt target gene expression. Pygopus also interacts with MLL2 and Ash2L (Chen *et al.*, 2010). Pygopus is recruited to the β -catenin/TCF complex by BCL9/Legless (Figure 9(c); Kramps *et al.*, 2002). Pygopus contains a plant homeodomain (PHD domain), which interacts with methylated histone H3 (Soliman and Riabowol, 2007). The PHD domain of Pygopus preferably binds dimethylated H3K4 upon interacting with BCL9 (Mosimann *et al.*, 2009), suggesting that Pygopus reads the 'histone code' and acts as an additional anchor for the β -catenin/TCF complex to chromatin. Parafibromin, a component of the PAF1 complex, is essential for the initiation and elongation steps of transcription through its interaction with RNA Polymerase II. The PAF1 complex interacts with the C-terminal transactivation domain of β -catenin and is required for transactivation (Figure 9(c)). Overexpression of Parafibromin can compensate for loss of BCL9/Legless *in vivo* (Mosimann *et al.*, 2006).

Other HMTs may also regulate Wnt-mediated transcription. For example, HMT SET8 directly interacts with TCF/LEF and regulates H4K20 monomethylation (H3K4Me1). Thus, Wnt stimulation increases H3K4Me1 levels at Wnt target gene promoters, indicating H3K4Me1 is a marker for gene activation in Wnt signaling (Li *et al.*, 2011). Dot1 (disruptor of telomeric silencing) is a lysine methyltransferase in *Drosophila*. Dot1 and its associated factors have been linked to H3K79 trimethylation and activation of Wnt/Wingless target genes in *Drosophila*, zebrafish, and human colorectal cancer cells (Mahmoudi *et al.*, 2010; Mohan *et al.*, 2010). However, DOT1L-mediated H3K79 methylation appears to be dispensable for Wnt pathway functions in the mouse intestine (Ho *et al.*, 2013).

Other Co-activators and Corepressors

β -Catenin interacts with many other co-activators and corepressors, such as the ATP-dependent chromatin remodeling

factors Brg-1/Brahma (Barker *et al.*, 2001) and the ATP-dependent helicase TIP49a/Pontin52 (Bauer *et al.*, 1998, 2000). Nuclear β -catenin antagonists ICAT and Chibby bind the C-terminus of β -catenin and disrupt the β -catenin/TCF complex (Tago *et al.*, 2000; Takemaru and Moon, 2000). Many transcription factors also interact and regulate the β -catenin/TCF complex. For example, a zinc finger protein, KLF4, interacts with both β -catenin and TCF and represses Wnt signaling in the intestine by inhibiting the binding of co-activator, p300/CBP (Evans *et al.*, 2010). However, the closely related transcription factor KLF5 highly expressed in the intestinal crypt compartment promotes cell growth and tumorigenesis by facilitating β -catenin-TCF-4 complex formation (Nakaya *et al.*, 2014; Guo *et al.*, 2015). In hepatocellular carcinoma SOX1 acts as a tumor suppressor. GST-pull-down and co-immunoprecipitation demonstrated that SOX1 interacts with β -catenin but not with the β -catenin/TCF complex (Tsao *et al.*, 2012). In mouse muscle progenitor cells, Barx2 and Pax7 have competing effects on Wnt effectors β -catenin and TCF-4. Barx2 promotes recruitment of β -catenin to TCF/lymphoid enhancer factor sites, while Pax7 represses Wnt/ β -catenin reporter and Barx2 effect (Zhuang *et al.*, 2014). In *Xenopus laevis*, co-injection of mRNA from β -catenin along with any member of the zinc finger family Zic (Zic1 to Zic5) leads to suppression of β -catenin transcriptional activity. Zic2 directly binds to TCF-4 HMG box while Zic3 interacts with overexpressed TCF1 (Pourelbrahim *et al.*, 2011; Fujimi *et al.*, 2012). Kindlin2, better known as a focal adhesion protein, was found to interact directly with active β -catenin and form a tripartite complex with β -catenin and TCF-4. Kindlin2 strengthens Wnt target gene expression in MCF7 breast cancer cells (Yu *et al.*, 2012). Some transcription factors not only enhance Wnt target gene expression but also shape genetic programs by binding to DNA elements found in a subset of Wnt target gene. Genome-wide analysis of *cis*-regulatory regions from colonic cells showed co-occupancy of CDX2 and TCF-4 across short distances. Another interesting example is the stem cell marker and transcription factor Ascl2 that binds DNA elements nearby WRE and drives the intestinal stem cell program (Schuijers *et al.*, 2015). Other signaling pathways also regulate Wnt signaling in the nucleus. TCF/LEF can be phosphorylated by Nemo-like kinase (NLK), which is activated by TAK1 (TGF β -activated kinase 1). The TAK1-NLK1 pathway inhibits the interaction of β -catenin/TCF complex with DNA (Ishitani *et al.*, 1999). Another kinase called TNIK is recruited by β -catenin on TCFs for phosphorylation and enhances Wnt target gene activation (Mahmoudi *et al.*, 2009).

Conclusions

Since the discovery of Wnt1 in 1982, our understanding of Wnt proteins, Wnt/ β -catenin and other Wnt signaling pathways, and their involvement in broad biological processes has exploded beyond anyone's imagination. Wnt signaling and its studies have permeated almost all realms of modern biological and biomedical research, and exciting discoveries are continuing to be made in and around Wnt signaling in development, stem cell, and cancer biology. As many fundamental questions of Wnt signaling remain to be understood, and the

potential of therapeutic targeting of Wnt signaling for cancer and disease treatment is yet to be fully realized, these unanswered questions and unmet needs present great challenges and also opportunities for generations of Wnt researchers.

Introduction

The formation of complex structures during the development of multicellular organisms is a very intriguing theme that raises many questions. The first answers came from a series of studies made in *Drosophila melanogaster* thanks to the development of genetic mosaics. Four tumor suppressor genes were identified, and a loss-of-function mutation in these genes resulted in overgrowth and reduced cell death (Tapon *et al.*, 2002; Lai *et al.*, 2005; Staley and Irvine, 2012). Products of these genes are the core component (the core kinase cassette) of the Hippo pathway (also known as the Salvador–Warts–Hippo pathway), and orthologs were discovered in mammals as well. The Hippo pathway is an evolutionarily conserved regulator of cell proliferation, organ size and shape during development, cell survival, cell competition, stem cell maintenance, metastasis, tissue regeneration, apoptosis, senescence, and differentiation (Figure 1). It is regulated by many factors such as planar cell polarity (PCP), apical-basal cell polarity (ABCP), cell–cell adhesion, contact inhibition, metabolism, mechano-transduction, senescence, and DNA damage (Fausti *et al.*, 2013; Harvey *et al.*, 2013; Strano *et al.*, 2013; Piccolo *et al.*, 2014; Sorrentino *et al.*, 2014; Figure 1). This pathway also cross-talks with other signaling players such as Notch, Wnt, Insulin-like growth factor/Epidermal growth factor receptor (IGF/EGF-R), transforming growth factor- β /bone morphogenetic protein (TGF- β /BMP), and Sonic hedgehog (Cho *et al.*, 2006; Baena-Lopez *et al.*, 2008; Karpowicz *et al.*, 2010). Dysregulation of the Hippo pathway is involved in tumorigenesis (Zhao *et al.*, 2008; Pan, 2010; Harvey *et al.*, 2013; Park and Guan, 2013).

The Hippo Pathway in *D. melanogaster*

The Hippo kinase cassette is composed of four tumor suppressor proteins: a member of the Sterile-20 family Serine-Threonine kinase, Hippo (Hpo) (Harvey *et al.*, 2003); a member of the Nuclear Dbf-2-related (NDR) family Serine-Threonine kinase, Warts (Wts) (Xu *et al.*, 1995); the scaffold protein interacting with Hpo, Salvador (Sav; also known as Shar-Pei) (Tapon *et al.*, 2002); and the Wts cofactor Mob as

tumor suppressor (Mats) (Lai *et al.*, 2005). Activation of Hpo and Wts involves intermolecular autophosphorylation. Activated Hpo phosphorylates Wts, Mats, and Sav bind and link together Hpo and Wts. Phosphorylated Sav activates Hpo kinase activity (Tapon *et al.*, 2002). Wts activity is crucial for the phosphorylation-dependent regulation of the transcriptional coactivator Yorkie (Yki) (Huang *et al.*, 2005; Figure 2). Yki promotes cell proliferation and survival and inhibits apoptosis (Buttitta and Edgar, 2007). Activated Wts/Mats phosphorylate Yki in three different sites (Ser111, Ser168, and Ser250), inhibiting its function (Huang *et al.*, 2005; Dong *et al.*, 2007). The phosphorylation of Ser168 creates a binding site for 14-3-3 proteins (these proteins recognize phosphorylated Serine or Threonine residues) that retain Yki in the cytoplasm, thus inhibiting its nuclear transcriptional coactivator function (Figure 2). Yki has two WW domains that enable interaction with short proline-rich or proline-containing motifs terminated with Tyrosine (PY motifs, i.e., PPXY) (Sudol and Hunter, 2000). Yki lacks its own DNA-binding domain and therefore interacts in the nucleus with different DNA-binding transcription factors such as Scalloped (Sd), Mothers against Dpp (Mad) (Oh and Irvine, 2011), Homothorax (Hth)-Teashirt (Tsh) complex (Peng *et al.*, 2009), and the interacting protein WW domain-binding protein 2 (Wbp2) (Oh and Irvine, 2010; Figure 2). This leads to increased cell proliferation and tissue growth (Staley and Irvine, 2012). In fact, some downstream targets of Yki are the *D. melanogaster* inhibitor of apoptosis protein 1 (Diap1), the growth-promoting microRNA gene *bantam* (*ban*) (Nolo *et al.*, 2006; Peng *et al.*, 2009; Oh and Irvine, 2011), dMyc, E2F1, and cyclins A, B, and E (Tapon *et al.*, 2002; Goulev *et al.*, 2008).

Upstream Regulators of Hippo Signaling in *D. melanogaster*

There are many upstream regulators of the Hpo kinase cassette. This strongly suggests that Hippo signaling functions as a network rather than a linear pathway. The two FERM (Four-point-one, Ezrin, Radixin, Moesin) domain-containing proteins Merlin (Mer) and Expanded (Ex) are tumor suppressors

Figure 1 The Hippo pathway is regulated by many factors and is involved in the regulation of several processes.

Figure 2 The core kinase cassette of the Hippo pathway in *D. melanogaster* is composed of Hpo, Wts, Sav, and Mats (in green color) and is regulated by many proteins, the majority of which are involved in cell polarity instauration (in blue and cyan colors). The Yki protein (in red color) is a transcriptional coactivator that promotes cell proliferation and survival; it is inhibited by the core kinase cassette.

whose mutation leads to Yki activation and causes tissue overgrowth (Hamaratoglu *et al.*, 2006). Mer and Ex bind to each other and co-localize at the apical membrane of polarized epithelial cells. A third partner in this complex is Kibra (Baumgartner *et al.*, 2010), another tumor suppressor protein (Yu and Guan, 2013) that, together with Mer and Ex, can phosphorylate and activate Hpo and Wts (Hamaratoglu *et al.*, 2006; Figure 2). Furthermore, Ex directly binds Yki and sequesters it in the cytoplasm, preventing its nuclear transcriptional function (Badouel *et al.*, 2009). Ex localization and function are regulated by the transmembrane protein Crumbs (Crb), which favors the acquisition of ABCP (Tepass *et al.*, 1990) and regulation of the Hippo pathway (Figure 2).

The ABCP is also regulated by a complex composed of Lethal giant larvae (Lgl), Disc large (Dlg), and Scribble (Scrib) that localizes to the basolateral membrane of polarized epithelial cells. Lgl inhibits the atypical protein kinase C (aPKC),

which activates the Ras association family member (dRassf) and the Jun Kinase (Jnk); both dRassf and Jnk inhibit activation of the core kinase cassette, increasing Yki activity. Rassf functions as a scaffold protein interacting with the Protein phosphatase 2A (PP2A) serine-threonine phosphatase complex, dSTRIPAK (Striatin-interacting phosphatase and kinase), which inhibits Hpo autophosphorylation and activation (Ribeiro *et al.*, 2010; Figure 2).

The atypical cadherins Fat and Dachsous (Ds) are involved in the acquisition of PCP and function as tumor suppressors, antagonizing the unconventional myosin Dachs, which activates the LIM-domain protein Zyx120 (Zyx). Zyx inhibits the activation of Wts in the core kinase cassette (Cho and Irvine, 2004; Rauskolb *et al.*, 2011); thus Fat, and Ds promote the activation of the Hippo pathway inhibiting Yki (Figure 2).

Other regulators of the Hippo pathway are the Sterile-20-like kinase TAO1, which phosphorylates and activates Hpo

Figure 3 The Hippo pathway in mammals shown conservation in the following key components: Mst1/2, Lats1/2, Sav1, Mob1, and YAP/TAZ (Hpo, Wts, Sav, Mats, and Yki orthologs, respectively). As in *D. melanogaster*, the core kinase cassette (in green color) inhibits YAP/TAZ (in red color) transcriptional coactivators. Fat and Ds roles in the Hippo pathway activation are not yet understood.

(Poon *et al.*, 2011) and the component of the adherent junction Ajuba LIM protein (Jub), which binds and inhibits both Sav and Wts, thereby increasing Yki activity (Das Thakur *et al.*, 2010; Figure 2).

The Hippo Pathway in Mammals

Many components of the *D. melanogaster* Hippo pathway have ortholog human counterparts that exhibit the same or opposite functions. The Hippo kinase cassette is composed by the Mammalian Sterile-20 family Serine-Threonine kinases 1 and 2 (Mst1/2) (Hpo orthologs) that phosphorylate the adaptor protein Salvador 1 (Sav1) (Salvador ortholog) (Tapon *et al.*, 2002), also termed WW45, the large tumor suppressor 1 and 2 (Lats1/2) AGC family kinases (Wts orthologs) (Yabuta *et al.*, 2000) and the Mps one binder kinase activator-like A and B (MOBK1A and MOBK1B) (Mats orthologs), also known as Mob1. Mst1/2 activate Lats1/2 by phosphorylation; the

interaction between Lats1/2 and Mob1 is necessary for Lats1/2 activation. This interaction is enhanced by Mst1/2 phosphorylation of Mob1. Mst1/2 kinase activity is enhanced through interaction with Sav1 (Yabuta *et al.*, 2000). Similar to the core cassette of *D. melanogaster*, Mst1/2 and Lats1/2 trigger a kinase cascade regulated by Sav1 and Mob1 and phosphorylate the co-transcription activators yes-associated protein (YAP) and its paralog Tafazzin (TAZ, also known as WWTR1) (Yki orthologs) (Sudol, 1994; Dong *et al.*, 2007; Figure 3). In response to cell density, YAP/TAZ phosphorylation at Ser127 and Ser89, respectively (like Yki Ser168), creates a 14-3-3 binding site and consequent YAP/TAZ cytoplasmic retention and inhibition. Thus, cell density-dependent activation of the Hippo pathway is involved in cell contact inhibition (Zhao *et al.*, 2012). Moreover, Lats1/2 can phosphorylate YAP at Ser381, triggering a consequent phosphorylation by the casein kinase 1 delta/epsilon (CK1δ/ε) at an additional residue. This event generates a 'phospho-degron' signal (conserved also in TAZ which is phosphorylated at Ser311, but not in Yki)

inducing recruitment of the E3 ubiquitin ligase SCF ^{β -TRCP} and consequentially YAP ubiquitin-mediated proteasome degradation (Zhao *et al.*, 2012; Figure 3).

YAP is a 65-KDa protein existing in two splicing variants (YAP1 and YAP2) and displaying a different number of WW domains (one WW domain in YAP1 and two tandem WW domains in YAP2), one binding domain for the interaction with transcription factors, highly conserved PDZ-binding motifs, and an activation domain like its paralog TAZ (Sudol *et al.*, 1994, 1995; Yagi *et al.*, 1999). YAP is ubiquitously expressed in many tissues as well as from blastocyst to perinatal developmental stages. In the nucleus, YAP interacts through the WW domain with the PPXY motifs of diverse transcription factors such as Runt-related transcription factor-1 (RUNX1, also known as acute myeloid leukemia 1 protein or AML1) and Runt-related transcription factor 2 (RUNX2), which regulates osteoblast differentiation of mesenchymal stem cells (MSCs), chondrocyte hypertrophy, and endothelial cell migration and vascular invasion in bone development (Yagi *et al.*, 1999). YAP also interacts with the TEA domain proteins/transcription enhancer factors (TEADs/TEFs) family (Zhao *et al.*, 2008; Figure 3), regulating cell proliferation, anchorage-independent growth, epithelial-mesenchymal transition (EMT), and embryonic stem cell (ESC) pluripotency. YAP induces the transcription of connective tissue growth factor (CTGF), cysteine-rich angiogenic inducer 61 (CYR61), or CCN family member 1 (CCN1), of Baculoviral Inhibitor of the apoptosis repeat-containing protein 1 (Birc2/cIAP1) Birc5 (also known as surviving), the epidermal growth factor family member amphiregulin (AREG), and Myc (Dong *et al.*, 2007; Lian *et al.*, 2010). YAP's interaction with Smad proteins regulates ESC and iPSC (induced pluripotent stem cells) pluripotency; YAP enhances ErbB-4 transcriptional activity (Varelas *et al.*, 2010). YAP also interacts with the p53 family member p73 (Strano *et al.*, 2001). In response to DNA damage, YAP imparts transcriptional target specificity to p73, favoring its recruitment onto apoptotic, instead of growth suppression targets. The tumor suppressor promyelocytic leukemia protein (PML) gene is a target of the transcriptional competent complex p73/YAP; this leads to an auto-regulatory feedback loop that stabilizes YAP and maximizes p73's pro-apoptotic activity (Strano *et al.*, 2001, 2005; Levy *et al.*, 2007; Lapi *et al.*, 2008). YAP also interacts with β -catenin, inducing the expression of canonical Wnt target genes (SOXS2 and SNAI2) (Heallen *et al.*, 2011). All these studies underline the pleiotropic YAP functions as oncoprotein or transcriptional coactivators of tumor suppressor proteins in response to different stimuli, resulting in differential spatial/temporal regulation of YAP activity and its downstream targets.

Similar to YAP, TAZ is inhibited by the Hippo pathway and functions as a transcriptional coactivator (Figure 3); it interacts with RUNX, TEADs/TEFs, peroxisome proliferator-activated receptor γ (PPAR- γ), thyroid transcription factor-1 (TTF-1), paired box 3 (Pax3), T-box transcription factor 5 (Tbx5), and Smads transcription factors, inducing cell proliferation, cell migration and invasion, ESCs pluripotency, and EMT (Hong *et al.*, 2005).

Upstream Regulators of Hippo Signaling in Mammals

Many regulators of the *D. melanogaster* Hippo pathway are also present in mammals. The neurofibromin 2 (NF2)/FERM

domain-containing protein 6 and 1 (Fmrd6/1)/WW domain-containing protein 1 and 2 (WWC1/2) tumor suppressor complex (Mer/Ex/Kibra orthologs) is involved in the mammalian ABCP; its localization at the apical membrane of polarized epithelial cells is mediated by Crumbs1-3 (Crb1-3) (Crb orthologs). This complex is involved in Lats1/2 activation and consequent YAP/TAZ phosphorylation and inhibition (Zhao *et al.*, 2012; Figure 3). Moreover, depletion of extracellular calcium or knockdown of Crb3 results in YAP/TAZ nuclear localization and transcription coactivation of their target genes (Varelas *et al.*, 2010). Mammalian Scrib activates the Hippo signaling inhibiting YAP/TAZ function (Chen *et al.*, 2012; Figure 3). Cell junction proteins such as Lin-7 homolog C (Lin-7C), membrane-associated palmitoylated protein 5 (MMP5, also known as Pals1), Pals1-associated TJ protein (Patj), and multiple PDZ domain protein (Mpdz) interact with the Hippo core kinase cassette (Varelas *et al.*, 2010; Figure 3). The Angiomotin-like proteins 1 and 2 (AMOTL1/2) maintain epithelial cell polarity and interact with YAP/TAZ in a phosphorylation-independent manner. This leads to sequestering of YAP/TAZ at the apical membrane and inhibition of their nuclear localization (Zhao *et al.*, 2011; Figure 3). AMOT also acts as a scaffold protein interacting with Mst1/2 and Last1/2, promoting YAP/TAZ phosphorylation (Zhao *et al.*, 2011). The α -catenin protein, a component of cell junctions, binds YAP-phosphorylated per 14-3-3 protein interaction, and this trimeric complex sequesters YAP at the apical membrane, preventing its activation (Schlegelmilch *et al.*, 2011; Figure 3). The Tyrosine-protein phosphatase non-receptor type 14 (PTPN14) is another factor involved in cell-cell junctions that directly binds YAP and sequesters it (Liu-Chittenden *et al.*, 2012; Figure 3). Several other proteins involved in ABCP integrity modulate the Hippo pathway: E-cadherin inactivates YAP; Ajuba/LIM domains containing 1 (Limd1)/Wilms tumor protein 1-interacting protein (Wtip) complex (Jub orthologs) activate Sav1 and Lats1/2, inhibiting YAP; Liver kinase B1 (LKB1) induces YAP phosphorylation; Nephronophthisis 4 (NPHP4) protein inhibits Lats1; and zona occludens-2 (ZO-2) induces YAP activation and nuclear localization, whereas ZO-1 represses TAZ activation (Yu and Guan, 2013; Figure 3).

The Hippo pathway responds to mechanical stretch or compression sensing the tensile state of the actomyosin cytoskeleton (dynamic of actin/myosin filaments assembly): in mechanical stretch conditions YAP/TAZ activity is increased and is repressed when cells are compressed (Dupont *et al.*, 2011; Piccolo *et al.*, 2014). YAP/TAZ activation is also regulated by cell-cell contact abundance: high cell density induces YAP/TAZ phosphorylation and cytoplasmic retention; disruption of cell-cell junctions results in YAP/TAZ activation and nuclear localization (Varelas *et al.*, 2010).

Lysophosphatidic acid (LPA), Sphingosine-1-phosphate (S1P), and thrombin inhibit Lats1/2, inducing YAP/TAZ activation in cultured cell binding transmembrane G protein-coupled receptors (GPCRs), and consequently activating the Rho GTPases Rho, Rac, and Cdc42 (Mo *et al.*, 2012; Yu *et al.*, 2012; Zhao *et al.*, 2012). It has been shown that GPCRs activate different heterotrimeric G proteins: $G_{\alpha_{12/13}}$, $G_{\alpha_{q/11}}$, and $G_{\alpha_{i/o}}$ induce YAP/TAZ activation, whereas G_{α_s} represses YAP/TAZ activity (Figure 3); thus glucagon, adrenaline, and dopamine induce Lats1/2-mediated phosphorylation of YAP/TAZ

Figure 4 In mammals, YAP is phosphorylated and activated by c-Abl in response to DNA damage. The YAP/PML/p73 complex translocates into the nucleus, promoting pro-apoptotic gene expression. ATM-phosphorylated YAP interacts with PML and signals p53 to induce senescence.

through increasing cyclic adenosine monophosphate (cAMP) amounts, resulting in Lats1/2 activation via Protein kinase A (PKA). Therefore, YAP/TAZ can be up- or down-regulated depending on different G α -activated proteins (Yu *et al.*, 2012). YAP/TAZ activities are also regulated by metabolism; in particular, activation of the mevalonate pathway, involved in cholesterol synthesis, causes YAP/TAZ activation and nuclear localization. Statins (drugs that reduce cholesterol levels in plasma) impair the mevalonate pathway and cause YAP/TAZ inactivation and cytoplasmic retention (Sorrentino *et al.*, 2014).

In response to stress-induced apoptosis, Mst1/2 are activated by autophosphorylation and caspase-dependent cleavage. This induces YAP phosphorylation and inactivation via a Lats1/2-independent mechanism (Zhou *et al.*, 2009). In response to DNA damage, Ataxia telangiectasia mutated (ATM) protein kinase activates the Rassf1-5 mammalian proteins, which have opposite functions compared to dRassf in *D. melanogaster*; they act as tumor suppressors that bind and activate Mst1/2, contrasting with Mst1/2 dephosphorylation by PP2A, and can also disrupt the inhibitory complex between

Raf1 and Mst2, promoting Mst1/2 and Lats1/2 interaction (Figure 4). In this way, YAP is phosphorylated at Tyr357 and relocalizes into the nucleus, where it binds to p73 and promotes its transcriptional pro-apoptotic activity (Matallanas *et al.*, 2007; Figure 4). By contrast, Rassf6 binds and inhibits Mst2, blocking Hippo signaling (Ikeda *et al.*, 2009). Moreover, in response to DNA damage, c-Abl kinase directly phosphorylates YAP at Tyr357, increasing protein stability and affinity for p73 (Levy *et al.*, 2008), whereas Akt/PKB kinase signaling mediates YAP phosphorylation at Ser127 and consequent cytoplasmic retention by preventing its binding to p73 and transcriptional activation of pro-apoptotic genes (Figure 4). YAP is also involved in the establishment of senescence through the activation of PML and p53 tumor suppressor proteins; in detail, loss of Werner-induced senescence activates ATM, which phosphorylates YAP and triggers the instauration of a transcriptionally active YAP/PML/p53 axis (Fausti *et al.*, 2013; Strano *et al.*, 2013; Figure 4). Together these findings highlight the fact that several intrinsic and extrinsic signals regulate the Hippo mammalian pathway.

Regulation of Organ Size, Stem Cell Self-Renewal, and Tissue Regeneration

In *D. melanogaster*, loss-of-function mutations of Hpo or Wts kinases or overexpression of Yki during development result in overgrown imaginal discs, leading to overgrowth of the corresponding adult structures (Staley and Irvine, 2012).

Organ size is finely regulated during development, and the Hippo signaling pathway plays a key role in this process (Camargo *et al.*, 2007). YAP/TAZ are expressed during mammalian early embryogenesis, binding the transcription factor TEAD4 and inducing Caudal type homeobox 2 (Cdx2) expression. Cdx2 is a transcription factor involved in trophoblast (TE; outer layer of the blastocyst stage embryo) formation (Camargo *et al.*, 2007). Loss of YAP suppresses Cdx2 expression, indicating that Hippo signaling is crucial for inner cell mass (ICM) segregation from the TE in blastocyst development. Moreover, YAP/TAZ localization is spatially regulated in the blastocyst stage embryo: YAP/TAZ are nuclear in TE and cytoplasmic in ICM, and this differential distribution is determinant for lineage specification in the preimplantation embryo (Camargo *et al.*, 2007). YAP/TAZ double knockout embryos die at the morula stage, before TE formation. It appears that the actin cytoskeleton structure is determinant for YAP/TAZ localization: TE cells are polarized, and thus have more F-actin and tension than ICM cells, which by contrast display more cell density and cell-cell contacts. Moreover, TE cells are exposed, and the GPCRs expressed on the surface might be regulated by external diffusible signals (Yu and Guan, 2013). Alteration in the expression or activity of upstream regulators results in deregulation of the Hippo pathway, which causes severe developmental defects.

The Hippo pathway defines either differentiation or reprogramming to a pluripotent state that is determined by the precise balance of growth factor amounts and cytoskeletal-associated cues. YAP is found in the nucleus of MSCs and ESCs; its nuclear localization and protein levels decline during MSC and ESC differentiation. Concomitantly, Hippo pathway activity is enhanced and YAP accumulates in the cytoplasm of differentiated cells (Lian *et al.*, 2010). YAP is also nuclear, and its expression is increased in iPSCs in conjunction with Octamer-binding protein 4 (Oct4), SRY (Sex-determining region Y), SRY-box 2 (Sox2), and Kruppel-like factor 4 (Klf4) transcription factor activation (Lian *et al.*, 2010); the pluripotent state of ESCs is also mediated by the YAP/TAZ/Smad2/3 complex in response to TGF- β /BMP signaling. It was observed that YAP/TEAD2 bind and activate OCT3/4 and NANOG promoters, and Lats1/2 inhibition of TAZ impairs reprogramming. Therefore, nuclear YAP/TAZ promote ESC self-renewal and iPSC reprogramming (Lian *et al.*, 2010). Notably, YAP/TAZ localization may be critical for cell fate, despite the fact that the impact of YAP/TAZ cellular compartmentalization during development is not well understood. Increasing nuclear YAP/TAZ promotes tissue regeneration, rising cell proliferation in the liver, pancreas, salivary glands, kidney, lung, heart, intestine, skin, and nervous system (Varelas, 2014). This requires that the Hippo pathway cross-talk with the Notch, Wnt, IGF/EGF-R, TGF- β /BMP, and Sonic hedgehog signaling pathways (Pan, 2010; Yu and Guan, 2013; Varelas, 2014).

Hippo Pathway Deregulation in Cancer

Loss-of-function mutation or epigenetic silencing of core kinase cassette components or activators of the Hippo pathway result in uncontrolled tissue overgrowth; moreover, YAP/TAZ overexpression induces transformation in mammalian cells and promotes tumorigenesis (Pan, 2010; Zhao *et al.*, 2012). Lats1/2 inhibit cell division cycle 2 (Cdc2 or Cdk1), favoring G2/M arrest; Lats2 also induces G1/S arrest. Thus, loss-of-function mutation of these genes leads to formation of tumors such as tissue sarcoma and leukemia (Yabuta *et al.*, 2000). Inactivation of NF2 promotes metastatic osteosarcomas, brain tumor development (meningiomas, schwannomas, and acoustic neuromas), hepatocellular carcinoma (HCC), bile duct tumors, and malignant mesothelioma, as do Mst1/2, Lats2, and Sav1 mutations (Johnson and Halder, 2014). Patients with NF2 mutation exhibit F-actin alterations and morphological changes, resulting in increased YAP activation. Fat4 and Dchs1/2 are frequently mutated in colorectal cancer; mutations in Sav1 and Mob1 are present in renal cancer cell lines and human melanoma, respectively (Johnson and Halder, 2014); Mst1/2, Lats1/2, and Rassf family genes are often silenced through epigenetic mechanisms, and YAP/TAZ genes are amplified in the lung, pancreas, esophagus, skin, colon, prostate, liver, ovarian and mammary gland carcinomas, medulloblastomas, and oral squamous-cell carcinomas; moreover, chromosomal translocation involving TAZ and calmodulin-binding transcription activator 1 (CAMTA1) results in a fusion gene TAZ-CAMTA1 being highly expressed in epithelioid hemangioendothelioma (Pan, 2010; Harvey *et al.*, 2013).

Elevated nuclear levels of YAP/TAZ are present in many solid tumors. This leads to increased cell proliferation, acquisition of cancer stem cell features, EMT (forming metastases), inhibition of senescence, reduced apoptosis, and drug resistance (Harvey *et al.*, 2013). Invasion and metastasis are common in advanced solid tumors and are responsible for the majority of deaths from cancer. Loss of cell polarity promotes YAP/TAZ activation in a positive feed-forward loop, inducing EMT and metastasis formation (Cordenonsi *et al.*, 2011). Increasing cell survival and reduced cell death are mediated by YAP/TAZ transcriptional up-regulation of anti-apoptotic B cell lymphoma 2 (Bcl-2) family members, cIAP1/2 anti-apoptotic proteins, MYC, CTGF, and CRY61 (Pan, 2010). Moreover, YAP overexpression can suppress anoikis cell death induced by anchorage-dependent cells detaching, promoting dissemination of invading cells and inducing metastasis formation; loss of E-cadherin (linked to EMT) function may also induce YAP/TAZ activation in metastatic cells (Yu and Guan, 2013).

Finally, the Hippo pathway interacts with many other signaling pathways, creating a complex network in which YAP/TAZ are emerging as a critical node integrating and decoding both oncogenic and tumor suppressor inputs (Harvey *et al.*, 2013).

Conclusions

The pleiotropic activities of the Hippo pathway have attracted unprecedented scientific interest. This has led to the

uncovering of many yet unexplored mechanistic insights into organ size regulation, stem cell self-renewal, tissue regeneration, DNA damage response, senescence, cell metabolism, and cancer development. It can be reasonably hypothesized that regenerative medicine and cancer treatment will strongly benefit from such knowledge.

The Notch Signaling Pathway

The Notch pathway was first described as a 'notch' seen in a *Drosophila* wing that resulted from haploinsufficiency of the Notch receptor. Subsequently, the Notch receptor, two ligands, Jagged and Serrate, and the downstream target gene *Hairy* were identified. In mammals this pathway has become more complex with four Notch receptors (Notch1, Notch2, Notch3, and Notch4), five ligands, and at least 10 *Hairy*-related genes. However, the basic mechanics of the pathway have been highly conserved across species. Briefly, the Notch receptors are each synthesized in a single polypeptide and then directed to the Golgi where they undergo glycosylation via fringe glycosyltransferases (Manic, Lunatic, and Radical) and proteolytic cleavage via a furin-like convertase. Glycosylation of the Notch receptors increases their affinity for specific Notch ligands. The two protein fragments resulting from proteolytic cleavage form a heterodimer in which the two domains are connected by a non-covalent calcium bond (Guruharsha *et al.*, 2012). Each receptor is thus composed of an extracellular domain and a transmembrane-intracellular domain (Figure 1). The extracellular domain is comprised of up to 36 epidermal growth factor (EGF) repeats, which bind Notch ligands, as well as a negative regulatory region (NRR) which binds to the transmembrane-intracellular domain, thereby preventing receptor activation. The NRR can be subdivided further into three Lin12/Notch repeats (LNR) and a heterodimerization domain (HD). The transmembrane-intracellular domain is non-covalently bound to the extracellular domain. The intracellular domain of Notch (ICN or NICD) is comprised of an RBPJk-associated module (RAM), ankyrin repeats (ANK), transactivating domain (TAD), and a proline, glutamic acid, serine, threonine (PEST) domain. The RAM and ANK domains allow ICN to interact with other proteins while the PEST domain is ubiquitinated, leading to degradation of the activated receptor (Li *et al.*, 2006). The five Notch ligands (Jagged1 (JAG1), JAG2, Delta-like ligand1 (DLL1), DLL3, and DLL4) are highly homologous to the two ligands first identified in *Drosophila*, Serrate and Delta, respectively. These ligands expressed on the cell surface of a signal-sending cell bind to and activate Notch receptors on neighboring cells. The ligands have a series of EGF repeats and a Delta-Serrate LAG-2 (DSL) domain. Additionally, the Jagged ligands also have a cysteine-rich domain. The DSL and EGF repeats cooperate to bind Notch receptors. Differences between the ligand structures result in a variety of different functions. Most of the ligands lead to receptor activation via a conformational change in the heterodimerization domain of the receptor with subsequent cleavage of the transmembrane domain. However, DLL3 can bind the Notch receptors but is unable to activate Notch, thereby inhibiting the level of signaling that occurs when other ligands bind to a receptor (Ladi *et al.*, 2005). The activating ligands also have preferences for different

receptors. This is partly based on the fringe glycosyltransferase modifications on the receptor EGF repeats from processing of the receptors in the Golgi. Glycosylated receptors have higher affinity for the Delta-like ligands compared to the Jagged ligands (Rampal *et al.*, 2005). Upon ligand binding and cleavage of the receptor, the signal-sending cells endocytose the ligand and the extracellular domain of the receptor. The remaining receptor is embedded in the membrane and is the target of enzymatic cleavage by ADAM17 (S2 cleavage) and gamma secretase (S3 cleavage). These sequential proteolytic cleavages from the transmembrane domain release ICN into the cytoplasm.

Upon release of the ICN from the transmembrane domain, the ICN translocates to the nucleus via two nuclear localization signals, and binds to a complex of ubiquitous transcription factor CBF-1, Suppressor of Hairless, Lag-2 (CSL or RBPJk). CSL normally forms a corepressor complex including SMRT, MINT, and SPEN, transcriptionally repressing CSL target genes. However, upon ICN binding, the corepressors are displaced and co-activators (i.e., mastermind-like) and histone acetyltransferases (i.e., CBP/p300) form an activating complex that upregulates target gene expression. The most common Notch/CSL target genes are in the *Hairy/Enhancer of Split* (HES) related family (HES1-HES7, HEY1, HEY2, and HEYL). These genes are basic-helix-loop-helix (bHLH) transcription factors which generally recruit corepressors of the groucho/TLE family to repress their target genes. Many other direct targets of Notch/CSL have been described in many cell type-specific patterns including MYC, Cyclin D1/3, CDK5, p21, Snail, PDGFRb, and many others. This downstream complexity provides for the diverse consequences of Notch signaling in different tissues.

Notch signaling is tightly controlled as low, moderate, and high levels and can have distinct consequences in a single cell type. Consequently, regulation of the Notch pathway occurs at multiple levels. Ligands on the signal-sending cell can be downregulated via ubiquitination by E3 ligases, Mindbomb and Neuralized, and undergo subsequent proteasomal degradation. Similarly, receptors can be degraded before the ICN is able to translocate to the nucleus. E3 ubiquitin ligases such as Deltex1 and Numb ubiquitinate the intracellular domain of the receptors, which leads to proteasomal degradation. Additionally, the Notch target gene NRARP can bind to ICN impairing the recruitment of a co-activation complex, forming another negative feedback loop. Finally, the HES family of Notch target genes can repress their own transcription, leading to oscillations of Notch downstream signaling.

Developmental Biology

Mechanisms

The Notch signaling pathway plays a key role in the developmental biology of all animals. It is involved in the growth

Figure 1 The Notch pathway. Notch ligand expressed on a signal-sending cell engages a Notch receptor on a signal-receiving cell and induces a conformational change in the Notch receptor, thereby allowing proteolytic cleavage of the receptor in the transmembrane domain. This releases the intracellular Notch receptor, which translocates to the nucleus, and binds to the CSL transcription factor, displacing corepressors and recruiting co-activators to drive the expression of HES family genes, and other target genes. See text for domain names.

and differentiation of many cell types, and has the ability to control cell fate decisions. Notch signaling can control the patterns of gene expression within a cell by either upregulating or downregulating various genes. These alterations of gene expression can either induce or impair differentiation. Thus, activating Notch in one cell type may impair differentiation, retaining stem-like properties in that cell type, while its activation may allow for differentiation down an alternate fate in another cell type. The distribution of Notch ligands and receptors can influence the cell fate decisions by three basic mechanisms (Figure 2; Lewis, 1998). During cell division the Notch pathway components can be asymmetrically distributed to two daughter cells (e.g., Numb), leading to different levels of Notch signaling and thus different cell fates. An additional mechanism of Notch influencing cell fate occurs during cell-cell interaction. Competitive Notch signaling can inhibit neighboring cells from adopting the same cell fate through lateral inhibition. This occurs in some cell populations when Notch signaling is induced in neighboring cells by presentation of Notch ligands in the signal-sending cell.

Signal-receiving cells downregulate expression of their own Notch ligand and thus decrease Notch signaling in the signal-sending cell. Ultimately, strong Notch signaling occurs in one cell and a lack of Notch signaling occurs in the other cell, thereby promoting different cell fates in neighboring cells. Another mechanism of how Notch influences cell fate decisions is boundary formation or inductive signaling. When a population of cells express Notch ligands they induce Notch signaling in neighboring cells, and this induces an alternate cell fate. Thus a group of cells can induce the differentiation of another group of cells, forming a boundary between different cell types. Whether these mechanisms occur in a particular cell type depends on expression of Notch pathway members and the downstream consequences of Notch signaling in a given cell type.

Using the cell fate mechanisms above, and its ability to regulate growth and apoptosis in a cell type-specific manner, Notch signaling plays numerous roles during embryogenesis, including critical roles in somitogenesis, neurogenesis, myogenesis, hematopoiesis, angiogenesis, among many others.

Figure 2 Mechanisms of cell fate determination or patterning. Through asymmetric segregation of Notch pathway genes (e.g., Numb), daughter cells can adopt distinct cell fates. Through cell–cell interaction, two similar cells can compete with Notch signaling, whereby Notch signaling inhibits expression of Notch ligands on the neighboring cell, resulting in high Notch signaling in one cell and low Notch signaling in the neighboring cell, and thus distinct cell fates. Finally, cells may express Notch ligands and induce Notch signaling in another group of cells, thereby inducing an alternate cell fate and creating a boundary of two cell types.

During these developmental processes, Notch signaling induces differentiation in some lineages while impairing it in others (Liu *et al.*, 2010).

Examples of Notch Roles in Development

During embryogenesis, Notch is important for anterior–posterior orientation, left–right orientation, and much of the anatomical layout of the organs and tissues. For example, during somitogenesis Notch signaling controls the formation of somite boundaries, which are the basis for the musculo-skeletal layout of the body. This pattern of distinct somites is achieved through the oscillatory negative feedback loop of HES1 creating waves of Notch signaling that influence the differentiation of multiple cell types along the embryo, for example, tendons, skeletal muscle, and cartilage (Rida *et al.*, 2004). In part, Notch activation allows myoblasts to differentiate at a slower rate, allowing the musculature to develop gradually while preventing the differentiation of muscle progenitor cells into mature muscle cells. Over the course of time, Notch signaling maintains progenitor cells that remain dormant until regeneration or growth of muscle is required (Bentzinger *et al.*, 2012).

Notch also plays a critical role in the development of the nervous system. Importantly, neural stem cells are maintained

by activation of the Notch signaling pathway, while inhibition of the pathway leads to differentiation into neurons (Hitoshi *et al.*, 2002). Notch controls the differentiation of multiple other cell types in the central and peripheral nervous system, such as Schwann cells and other glial cells.

Another system where Notch signaling plays multiple distinct roles is the hematopoietic system. Both activation and inactivation of Notch at specific times is imperative for the development of multiple lineages of hematopoietic cells (Kushwah *et al.*, 2014). During embryogenesis, Notch signaling directs development of definitive hematopoiesis via enabling the first hematopoietic stem cells to develop in the peri-aortic region. Later in development, Notch signaling appears to maintain the self-renewal capacity of hematopoietic stem cells. Stronger Notch signaling promotes differentiation toward the T cell lineage at the expense of B cell development. Interestingly, Notch signaling is then required in late B cell development to generate marginal zone B cells. Notch also plays multiple roles in myeloid lineages, though these are less well understood (Bigas *et al.*, 2012).

Many aspects of blood vessel development are dependent on Notch signaling. For example, Notch receptors 1 and 4 along with ligands DLL4 and JAG1 direct the specification of arteries versus veins, and contribute to new vessel sprouting and differentiation between endothelial and vascular smooth muscle cell fates (Fouillade *et al.*, 2012).

Notch also plays a role in the development of the liver, pancreas, skin and intestine, among many others. For a comprehensive review of Notch signaling in developmental processes, see Andersson *et al.* (2011).

Pathology

Given the broad effects of Notch signaling on normal development, it is not surprising that alterations in the Notch pathway will lead to abnormal development and disease. Indeed several disorders have been linked to mutations in Notch pathway members (Figure 3; Penton *et al.*, 2012).

For example, over 90% of patients with Alagille syndrome carry a micro-deletion or inactivating mutation in the Notch ligand JAG1 (Suskind and Murray, 2007), and a subset of the remaining patients carry mutations in the receptor Notch2 (Kamath *et al.*, 2012). This syndrome includes abnormal development of biliary ducts (in the liver), abnormal cardiac development leading to aortic valve dysfunction or Tetralogy of Fallot, abnormal vertebral development, as well as ocular and renal abnormalities. Cardiac abnormalities can also occur with Notch1 mutations, which have been found in patients with familial aortic valve disorders. Similarly, Notch3 receptor mutation or deletion leads to vascular abnormalities and is the major cause of CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy), a disorder characterized by migraine headaches, stroke, and dementia. These effects are due to loss of vascular smooth muscle leading to constriction of cerebral arteries, recurrent strokes, and specifically loss of white matter (Joutel *et al.*, 1996). Another example of musculoskeletal effects is revealed through mutations in the Notch ligand DLL3 in patients with spondylocostal dysostosis (SCDO). Aberrant Notch signaling leads to bone fusion and alignment issues, particularly

Figure 3 Notch pathway mutations in syndromes and cancer. Notch receptor ligand mutations can either activate (blue) or inhibit (red) Notch signaling. Specific receptor or ligand in parentheses. Schizophrenia (Schizo), Adams-Oliver syndrome (AOS), squamous cell carcinoma (SCC), cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), T cell acute lymphoblastic leukemia (T-ALL), non-small-cell lung cancer (NSCLC), adenoid cystic carcinoma (ACC), chronic lymphocytic leukemia (CLL), non-Hodgkin lymphoma (NHL), Hajdu-Cheney syndrome (HCS), spondylocostal dysostosis (SCDO). See text for domain names.

in the ribs and spine (Tumpenny *et al.*, 2003). Interestingly, DLL3 is an inhibitory Notch ligand, which when expressed in a cell can bind Notch receptors in the Golgi and lead to their degradation. Thus, these DLL3 mutations lead to a loss of repression of Notch signaling, disrupting somitogenesis, and thus skeletal development (Chapman *et al.*, 2011). Rarely, mutations in HES7 or Lunatic Fringe are also found in patients with SCDO. Aberrant Notch signaling has a variety of consequences on bone development and disorders (Zanotti and Canalis, 2013). Similarly, five of six patients with the osteoporotic skeletal disorder Hajdu-Cheney syndrome (HCS) had activating mutations in Notch2 (Isidor *et al.*, 2011), suggesting Notch2 activation is involved in development of HCS. Finally, combined effects on vascular and musculoskeletal development can also be seen in patients with Adams-Oliver syndrome (AOS), a defect in skin and bone development of the head and distal extremities. Mutations in Notch1 or CSL were found in several families (Hassed *et al.*, 2012). Like Alagille syndrome, cardiac and vascular defects were also found in some patients with these mutations (Stittrich *et al.*, 2014).

Notch pathway dysregulation is also involved in schizophrenia, polycystic kidney syndrome, and Mayer-Rokitansky-Küster-Hauser syndrome (genital aplasia), further revealing the broad consequences of aberrant Notch signaling.

Importantly, Notch signaling has been found to be a major feature of cancer in many different tumor types. Indeed, Notch can have oncogenic or tumor-suppressor roles depending on

tissue or cell type (Lobry *et al.*, 2014). The first oncogenic role for aberrant Notch was described in T cell acute lymphoblastic leukemia (T-ALL) and lymphoma, where the discovery of activating Notch1 mutations occur in >50% of patients with T-ALL (Weng *et al.*, 2004) as well as other hematologic malignancies. Indeed, constitutive Notch activation leads to differentiation arrest in T cell progenitors and directly contributes to T cell malignancies in mice and humans. In addition, activating mutations in Notch1 or Notch2 have been found in 10–15% of chronic lymphocytic leukemia (CLL) patients (Puente *et al.*, 2011), and in several types of non-Hodgkin lymphoma (NHL) (Martinez *et al.*, 2014).

In other tumor types activating mutations in Notch receptors occur in smaller subsets. Notch1 mutations have been identified in 10% of non-small-cell lung cancer (Westhoff *et al.*, 2009) and Notch1/2 mutations in 10% of adenoid cystic carcinoma (ACC) (Stephens *et al.*, 2013). Additionally, rare translocations of Notch1 or Notch2 and amplification of Notch4 have been seen in breast cancers (Andre *et al.*, 2009).

In contrast, inactivating mutations of Notch1 or Notch2 occur in 75% of cutaneous squamous cell carcinomas (SCC) (Wang *et al.*, 2011), and less frequently in SCC arising in other tissues, such as the head and neck (Agrawal *et al.*, 2011; Stransky *et al.*, 2011). Such mutations either impair the function of the Notch receptors or lead to incomplete or unstable forms of the receptors, which are rapidly degraded. In these cancers, Notch signal appears to play a tumor-suppressor role.

These are a few examples of the role of aberrant Notch signaling in cancer, with additional roles for Notch activation in melanoma, colorectal adenocarcinoma, pancreatic carcinoma, medulloblastoma, among others. Additional tumors where Notch plays a tumor-suppressor role include B cell acute lymphoblastic leukemia, acute myeloblastic leukemia, small-cell lung cancer, hepatocellular carcinoma, among others. It is further reviewed in Ntziachristos *et al.* (2014).

Summary

In summary, the Notch pathway is a fundamental regulator of development in many tissue types. Not surprisingly, aberrant Notch signaling leads to multiple developmental abnormalities and Notch can play both oncogenic and tumor-suppressor roles in a wide variety of cancer types. The diversity of ligands, receptors, and downstream consequences make Notch a complex pathway requiring a detailed analysis of Notch signaling in each biologic system.

Glossary

3₁₀-Helix It is a type of protein secondary structure characterized by amino acids arranged in a right-handed helical structure.

The Domain Perspective of Protein Architecture and Function

Protein structure and function is dictated by the protein amino acid sequence. Proteins similar in amino acid sequence fold into structures that are similar and often have similar function. However, the overwhelming complexity of protein sequences and structures makes it difficult to identify some pattern in the apparent disorder. Soon it became clear, however, that proteins can be looked at from a higher, less-detailed perspective as a sequence of domains. Domains are peptide units, 50 to several hundreds of amino acid long, that are found repeated in several instances in proteomes and can be recognized on the basis of sequence homology. Domains have the property of being able to fold independently from the rest of the protein they are embedded in and are modular. To put it simply, each domain has a function, either enzymatic or structural – most often the ability to interact with other peptides – and the combinatorial assembly of a subset of domains in different protein instances contributes to build a versatile diversity in the proteome. The Simple Modular Architecture Research Tool (SMART) database (see Relevant Website section) annotated 1191 domain families in July 2014. For historical reasons, the discovery and the characterization of the so-called SRC homology (SH) domains contributed to the establishment of a signaling model based on a modular view of protein structure and function and will be described in some

detail in this article. The SH2 and SH3 domains are prototype modules that can promote the formation of signaling complexes in response to changes in the environment sensed by a cell.

A Brief History of the Discovery of SH Domains

In the mid-1980s, scientists studying oncogenic viruses realized that the SRC and ABL families of non-receptor tyrosine kinases share three regions of sequence homology. Although the first region SH1 (for SRC homology region 1) was soon identified as the kinase domain, the functions of the other two (SH2 and SH3) were not immediately clear. The observation that mutations either in the SH2 or the SH3 domains could have either positive or negative effects on the ability of the SRC protein to transform cells pointed to the prominent role played by these domains in the regulation of the enzymatic function of the protein containing them. Soon after, protein database searches revealed that these two domains are not restricted to non-receptor tyrosine kinases, but are present in a variety of protein contexts with apparently unrelated function. This observation implied that SH2 and SH3 domains are modular and confer some independent function that is not necessarily related to the protein kinase activity. The finding that many proteins containing SH3 or SH2 domains are involved in signal transduction immediately

alerted the researchers to investigate their prominent role in transferring regulatory signals from the cell membrane to the nucleus. The breakthrough came from the discovery that these domains can bind to peptides that share a common structure and/or sequence features. A variety of experimental approaches showed that SH3 domains have preference for peptides characterized by several prolines while SH2 bind to peptides containing a phosphorylated tyrosine. These seminal observations were instrumental in stimulating a large number of studies that eventually lead to the description of a complex network of interactions that underlies most of the cellular processes.

SH3

SH3 domains are about 60–70 residues long and are found in a large number of proteins involved in different cellular processes such as intracellular signaling, protein trafficking, cytoskeletal organization, and immune response. The SH3 domain family is one of the most populated family in many proteomes, from yeast to man. The number of SH3 domains roughly correlates with genome complexity, the human, drosophila, and yeast genome encoding about 300, 90, and 28 members, respectively. Although most SH3-containing proteins have a single SH3 domain, it is not uncommon to find

Figure 1 Structure of the SH3 domain. (a) Alignment of 10 representative SH3 domains to illustrate conserved positions. Conserved residues are colored according to amino acid type. Arrows above the alignment map the positions of β -strands. (b) Three-dimensional ribbon model of the SH3 domain of the kinase Abl complexed with the high-affinity peptide ligand 3BP-1 (APTYPPPLPP). β -Strands are depicted as red arrows. Some of the residues described in the text are shown with a ball and stick representation.

proteins with multiple copies and as many as five SH3 domains can be found in the dynamin binding protein, DNMBP, or in intersectin. The human proteome encodes 207 proteins containing a total of about 300 SH3 domains.

Structure

Even though the primary sequences of SH3 domains show little conservation, typically 25% between any two SH3 domains (Figure 1(a)), their three-dimensional fold is highly similar (Figure 1(b)).

The domain structure consists of five (or six) β -strands arranged in two perpendicular β -sheets to form a very conserved β -barrel. Each β -sheet is built from three antiparallel β -strands linked by three variable loops that are normally referred to as RT-loop, n-Src loop, and distal loop; the fourth and fifth strands are separated by a short 3_{10} -helix (Figure 1(b)).

The surface utilized by most SH3 domains to bind their targets can be schematically split into three discrete patches consisting of two hydrophobic grooves, lined mainly by highly conserved hydrophobic residues and a specificity pocket (Musacchio *et al.*, 1992; Yu *et al.*, 1992). The shape and chemical characteristics of the specificity pocket is molded by the variable and flexible RT and n-Src loops that play an

important role in modulating recognition specificity within the domain family (Feng *et al.*, 1995).

Target Recognition Motifs

The observation that many SH3 ligands contain proline-rich motifs (Ren *et al.*, 1993) combined with the analysis of a growing number of structures of SH3 domains complexed with their ligands led to the formulation of a general SH3 binding model (Feng *et al.*, 1994; Lim *et al.*, 1994; Figure 2). Most SH3 ligands contain an (XPxXP) motif where P is a proline and X a hydrophobic residue. The two XP moieties in the core motif, when complexed with the SH3 surface, occupy the two hydrophobic grooves in the peptide-binding surface (Figures 1 and 2). The specificity pocket often contains negative residues and can host a positively charged side chain flanking the peptide ligand core motif. Some domains, such as the ABL SH3 domain in Figure 1, do not have the negative charge in the specificity pocket and preferentially bind peptides containing a large hydrophobic residue instead of the typical positively charged residue.

SH3 ligands bind to their receptors in a left-handed polyproline type II (PPII) helical conformation in either of two opposite orientations depending on the position of a positive

residue in the peptide sequence (Figure 2(b)). This ability to bind in the two orientations is a consequence of the pseudo symmetry of the left-handed PPII helix and it is also observed in other domains that bind poly-proline peptides. Positively charged residues, such as arginine and lysine, in the ligand peptide play an important role in the binding to SH3 domains, not only by providing additional binding energy, but also by orienting the ligand with respect to the SH3 domain binding surface (Feng *et al.*, 1994). In fact, depending on the position of the positive residue, either at the N- or C-terminus of the core motif, peptide ligands adopt either an N-to-C or C-to-N orientation. Peptides that conform to the consensus R/Kx#PX#P (where # is normally a hydrophobic residue) bind in a type I orientation, while peptides that are characterized by Px#PxR/K (type II motif) bind in the opposite orientation (Figure 2(b)). The SH3 domain of the protein kinase ABL, one of the most studied SH3 domains, is atypical since it binds to ligands in a class I conformation that have a tyrosine (or a large hydrophobic residue) at position P-3 (for residue nomenclature see Figure 2) in place of the positively charged side chain.

Atypical Binding Motifs

Two *in vitro* technologies, phage display and screening of peptide arrays, have made possible large surveys of SH3 domain binding preference (Tong *et al.*, 2002; Tonikian *et al.*, 2009). These studies have confirmed that most SH3 domains show preference for peptides that conform to classical type I or type II binding motifs. Over recent years, however, a growing number of reports have revealed several interactions that involve binding of the core PXXP-motif docking surface of the SH3 to a peptide that do not contain a classical #PX#P consensus. These findings have challenged the generality of the classical model (Saksela and Permi, 2012). In addition, it is possible that the perceived dominance of classical Class I or Class II motifs rather reflects a historical focus on non-receptor tyrosine kinases and that the relative prevalence of non-consensus ligands might eventually turn out to be significantly higher than currently appreciated.

For instance, the SH3 domain of amphiphysin 1 was shown to prefer class II peptides containing an arginine instead of an aliphatic residue at position P0 (Cestra *et al.*, 1999; Grabs *et al.*, 1997). A second atypical subfamily of SH3 domains includes the three CIN85 SH3 domains. This subfamily specifically selects peptides containing the consensus sequence PX(P/A)XXR (Musacchio *et al.*, 1992; Kurakin *et al.*, 2003; Yu *et al.*, 1992). Regions containing peptides conforming to this consensus were confirmed as the CIN85 binding sites in its established physiological partners Cbl-b, c-Cbl, BLNK, AIP1, SB1, and CD2. A similar consensus (PPPVIAPRP) was also observed in a region of PAK2 that is required for binding the SH3 domain of α PIX indicating that CIN85 and α PIX may have evolved similar strategies in peptide recognition (Feng *et al.*, 1995; Manser *et al.*, 1998).

More strikingly, some SH3 were shown to be able to accommodate peptides that are not proline rich. For instance, the SH3 domain of EPS8 binds to ligands that contain a PxxDY motif (Ren *et al.*, 1993; Mongiovi *et al.*, 1999). A second striking example of an atypical target peptide that is capable of binding to SH3 domains is the tyrosine-based peptide (RKXXYXXY)

found in the immune cell adaptor protein SKAP55. Peptides containing this motif can bind to a subset of SH3 domains, such as those of FYN and FYB, that prefer consensus Class I PXXP ligands in random peptide screening experiments (Feng *et al.*, 1994; Kang *et al.*, 2000; Lim *et al.*, 1994).

All the atypical binding modes described so far require the peptide to contact the same binding surface that was described for the classical type I and type II interactions (Figures 1 and 2), irrespective of whether the binding peptide contains a PxxP motif or not. However, a few SH3 domains have acquired in evolution the capacity to exploit different patches of their surface to promote the formation of functional complexes.

One classical example of an SH3-mediated interaction that does not involve a peptide in PPII conformation is the binding of the SH3 domain, a protein involved in peroxisomal assembly, PEX13p, to PEX5p. PEX5p does not contain a poly-proline motif and binds in α -helical conformation to an SH3 region that is different from the PPII peptide-binding pocket. Consistently, PEX14p, another peroxin which recognizes PEX13p SH3 via a canonical PXXP interaction, does not compete with binding of the PEX5p α -helical peptide (Feng *et al.*, 1994; Pires *et al.*, 2003). Interestingly, GRB2 and the guanine nucleotide exchange factor VAV were shown to form a complex via hetero-dimerization of their SH3 domains.

In summary, most of the 300 human SH3 domains *in vitro* bind to peptides that conform to classical class 1 and class 2 consensi. However, the list of atypical binders is growing, showing that the SH3 fold is very versatile and offers the possibility for exploring alternative binding modes of peptide binding and that this versatility has been extensively used in evolution.

SH2

The propagation of cell signals is often mediated by the reversible phosphorylation of specific tyrosine, threonine, or serine residues, which promote the formation of dynamic protein complexes. It was therefore exciting when it was proposed that SH2 domains preferentially bind peptides containing phosphorylated tyrosines (Tong *et al.*, 2002; Anderson *et al.*, 1990; Tonikian *et al.*, 2009; Mayer and Hanafusa, 1990). Together with tyrosine kinases and phosphatases, SH2 domains play a prominent role in many signaling processes by taking the 'reader' role in monitoring the modification events that add or remove phosphates from tyrosines in response to changes in the cell environment.

The SH2 domain is not the only module that is able to recognize phosphorylated tyrosine residues (Saksela and Permi, 2012; Yaffe, 2002). For instance, the phospho-tyrosine binding (PTB) domain, first identified in the adaptor proteins SHC and in the insulin receptor substrate 1 (IRS1), has the capability to bind phospho-tyrosines. The SH2 family though is by far the largest family displaying this property and, as such, has a central role in the signaling events triggered by receptor tyrosine kinases.

The development of a pTyr cell communication system, based on the interplay between tyrosine kinases, phosphatases, and proteins containing SH2 domains is likely to have played a considerable role in facilitating the evolutionary shift from unicellular organism to multi-cellularity (Cestra *et al.*, 1999;

Figure 3 Structure of the SH2 domain. (a) Alignment of 10 representative SH2 domains to illustrate conserved positions. Conserved residues are colored according to amino acid type. Green boxes and red arrows above the alignment map the positions of α -helices and β -strands respectively. (b) Three-dimensional ribbon model of the SH2 domain of the kinase SRC in complex with the high-affinity phospho-tyrosine peptide ligand PQPYEEIP. Helices and strands are depicted as green ribbons or red arrows respectively. Some of the residues described in the text are shown with a ball and stick representation.

Lim and Pawson, 2010; Grabs *et al.*, 1997). It is therefore not surprising that functional SH2 domains are only found in the proteomes of metazoan. Homology searches in the human proteome identify 120 SH2 domains in 110 proteins.

Structure

The SH2 domain is approximately 100 residues long and folds into a conserved structure formed by an N-terminal α -helix (αA) and a 'core' four-stranded antiparallel β -sheet (βA , βB , βC , βD) followed by second β -sheet ($\beta D'$, βE , βF) that precedes an additional α -helix (αB) and a short C-terminal β -strand (βG) (Figure 3).

The structures of SH2 domains complexed with peptide ligands show the phospho-peptide hosted in two binding clefts that are separated by the core β -sheet (Pascal *et al.*, 1994; Lee *et al.*, 1994; Eck *et al.*, 1993; Figure 3(a)). The first cleft is positively charged and makes numerous important contacts with the phospho-tyrosine while the second cleft is much

more variable and is responsible for the selective recognition of residues that are C-terminal to the phospho-tyrosine.

The negatively charged phosphate inserts into a cleft in the core β -sheet, where its oxygen atoms are coordinated by two conserved arginines at position $\beta B5$ (β -strand B, position 5), and $\alpha A2$ and a histidine at $\beta D4$ (Figure 3(b)). These pTyr interactions are conserved in most SH2 domains and provide roughly half of the ligand binding energy. Consistently, mutations in either Arg $\beta B5$ or His $\beta D4$ abolish pTyr-specific binding (Marengere and Pawson, 1992).

Target Recognition Motifs

SH2 domains bind pTyr-containing peptide ligands with an affinity that is 1000-fold higher than that of the corresponding non-phosphorylated peptide suggesting that most of the binding energy depends on the interactions between the phosphate and the positively charged residues in the pTyr binding pocket (Piccione *et al.*, 1993). However, most SH2 domains display specificity and discriminate phospho-tyrosine

Figure 4 SH2 domain recognition motifs. The figure illustrates, by a sequence logo representation, the preferred motifs bound by 6 representative SH2 domains. The size of the font matches the level of conservation of the specific residue in a large collection of peptides that bind the domain in *in vitro* experiments. The green Y represents the phosphorylated tyrosine.

peptides on the basis of the phospho-tyrosine sequence context. Specificity is determined by the contacts with residues in the loop regions (CD, DE, BG) and strands β D and β E which define the specificity pocket in the SH2 domain. These loops and strands are more variable in sequence and are responsible for making contact with residues C-terminal to the pTyr (**Figure 1(b)**).

For instance, the GRB2 SH2 has a very strong preference for the presence of an asparagine two residues at the carboxy-terminus of the phosphorylated tyrosine (pYxNxx). Recent proteome wide peptide array experiments have allowed a nearly complete characterization of the recognition specificity of the entire family of the human SH2 domains (**Tinti et al., 2013**). These studies have pointed out that SH2 domains discriminate their targets by making important contacts with residues from position +1 up to +4 in the ligand peptide. For example, the SH2 domain of the FES, MST, SYK, RASA1, and BRDG1 proteins prefers the pYExxx, pYDxxx, pYxxLx, pYxxPx, or pYxxxP respectively (**Figure 4**). In addition to residues that in specific positions favor binding and confer specificity non permissive amino acid – residues that oppose binding – could play a role in shaping SH2 domain recognition specificity (**Liu et al., 2012**).

The preference of SH2 domains for specific phospho-peptide motifs has important biological consequences as demonstrated by the effects of manipulating their binding selectivity. Replacing a Thr at position EF1 in the SRC SH2 domain with a Trp, as in GRB2, determines a dramatic change in specificity with a strong preference for peptides having an Asn at the +2 position, virtually identical to that of GRB2 (**Marengere et al., 1994**). This demonstrates that domain selectivity can be attributed to specific residues. In addition, it was possible to show that binding selectivity correlates with the biological activity since SH2 domains are functionally interchangeable only if they share the same binding specificity.

Specificity and Promiscuity

The results of proteome wide studies of SH3/2 domain binding specificity, as outlined in the previous sections, have

shown that little divergence in domain sequence homology can account for relatively large changes in binding specificity. This is consistent with the observation that a few amino acid changes are sufficient to induce a specificity shift in peptide recognition modules (**Marengere et al., 1994; Panni et al., 2002**) and has implications for the interpretation of the observed rapid evolution of protein interaction networks (**Kiemer and Cesareni, 2007**).

Although individual SH3 and SH2 domains in general favor binding to peptides containing particular amino acid sequence motifs, these differences are often subtle and a considerable level of interaction promiscuity can be observed in experiments carried out *in vitro*. Any given domain can bind to a variety of short peptides with similar moderate affinity and many peptides in the proteome can bind to a number of different domains. Indeed there isn't really much room for specificity in the core peptide-binding grooves. Only a few core ligand residues directly contact the SH domains. Moderate affinities low (μ M to high nM) also imply that the interactions mediated by these domains are highly dynamic. In fact, the relatively rapid off rates imply that SH3/2-mediated interactions have the potential to reorganize, depending on available binding partners.

It has been argued that a certain level of promiscuity and redundancy can confer some robustness to the system (**Castagnoli et al., 2004**). For instance, a protein that exploits interactions mediated by its SH3 domain to localize to the cytoskeleton may find it advantageous to have several possibilities to dock to different cytoskeletal proteins.

However, a high degree of selectivity is achievable *in vivo*. Experiments in yeast have shown that at least one SH3 ligand peptide is absolutely selective for its known biologically relevant binding partner and does not detectably bind to any of the other 26 SH3 domains of the yeast *Saccharomyces cerevisiae* (**Zarrinpar et al., 2003**). In addition, the ability to link to several partners may contribute to the crosstalk between different pathways.

The limited specificity detected *in vitro*, which in several cases contrasts with the selectivity observed *in vivo*, implies that SH3/2-mediated interactions can be highly dependent on the molecular and cellular context. Several examples

have been reported, where additional surfaces on the domain and its peptide target within the physiological protein context can confer much greater affinity and/or specificity to an interaction. In addition other domains on the two potential binding partners can also contribute to overall specificity.

The studies described so far establish that the amino acid sequence of an SH3/2 domain can be used to predict its target peptide preference. This in turn has some predictive value for identifying physiologically relevant partner proteins for that domain. Although it is reasonable to assume that domain peptide-ligand pairs that have evolved the highest binding affinities and selectivities are likely to be physiologically relevant, the intrinsic specificity built into the fold of individual SH2 and SH3 domains are only one of the many factors that influence partner selection. To mention a few, the protein localization in cell compartments and the protein expression profiles of different cell types confer compartment and cell specificity to the functional complexes that are formed.

Function

The SH3 and SH2 folds are optimized for binding poly-proline type 2 helices or phospho-tyrosine peptides respectively, and

this is what they only do in their physiological context, if we neglect a few exceptions.

However, nature has exploited the ability to splice these simple functions to a variety of additional modular functions embedded in other domains, to develop, by a sort of 'molecular Lego,' a complex pattern of versatile regulatory networks. For instance, the combination of SH2 domains with either a kinase or a phosphatase domain may generate a positive or a negative feedback. The phosphorylation of a receptor can recruit via an SH2 domain a kinase or a phosphatase that either adds an extra phosphate (positive feedback) or removes an existing one from a different residue (negative feedback) (Pawson, 2004; Tonks and Neel, 2001). The combinatorial nature of the gene splicing processes that may occur in evolution offers a practically unlimited number of functional possibilities. We will describe here a few paradigmatic cases selected from a growing list of fascinating examples.

It needs to be pointed out that there is a fundamental difference between the interactions mediated by SH3 and by SH2 domains. The first ones are somewhat static and can only be affected by conformational changes of the domain or its target, which may result in affinity modulation. Alternatively, variations of the local concentrations of the partners or of competitor ligands may change the relative abundance of the complexes that are formed by the law of mass action.

Figure 5 Mechanisms that regulate pathway activation. The two cartoons illustrate two examples by which intramolecular interactions mediated by SH domains modulate enzyme activity. (a) Regulations of RAS activation by re-localization of the SOS protein. (b) Regulation of activity of non-receptor protein kinases.

Complexes formed by the interaction between SH2 domains and phosphoproteins on the other hand are more dynamic since they can be switched on and off by changing the phosphorylation status of the target peptides either in *cis* (within the same protein) or in *trans* (in another protein). These types of interactions are ideally suited to modulate the cell response to growth signals that activate receptor tyrosine kinases as in the cases briefly described below.

Recruitment of the Son of Sevenless Protein to the Membrane

One of the most common function of SH domains is that of facilitating the colocation of proteins, for instance enzymes and substrates, thus promoting specific signaling cascades and pathway activation. A prototypic example of such a regulatory mechanism is offered by the re-localization of the son of sevenless (SOS) protein to activate the MAP kinase pathway (Figure 5(a)).

The stimulation of the MAP kinase growth pathway is triggered by the activation of the RAS small GTPase, which, in the active state, turns on the MAP kinase cascade (Katz *et al.*, 2007). RAS is attached to the membrane via a prenyl group and in the absence of growth factors it is in the inactive guanosine diphosphate (GDP) bound conformation. To be activated it needs to encounter the SOS protein that can promote the exchange of the GDP with the guanosine triphosphate (GTP). SOS, however, is normally located in the cytoplasmic compartment where it forms a complex with the growth factor receptor-bound protein 2 (GRB2) adaptor by docking two proline-rich regions to the two SH3 domains in GRB2. After stimulation by growth factors the growth factor receptor dimerizes and promotes the phosphorylation of a number of tyrosines in its cytoplasmic tail. Some of these phosphopeptides have affinity for the GRB2 SH2 domain thus promoting the prompt re-localization to the membrane of the GRB2-SOS complex. The re-localization of SOS to the membrane promotes the activation of RAS triggering the RAF/MEK/ERK phosphorylation cascade.

Modulation of the Activity of SRC Kinase and the SHP-2 Phosphatase

A second interesting and well-characterized mechanism controls the activity of non-receptor tyrosine kinases (Figure 5(b)). Many soluble tyrosine kinases such as, for instance, SRC and ABL are found tethered to SH3 and SH2 domains. Aside from guiding the enzymatic activity to specific substrates, these domains have evolved the ability to regulate the activity of the kinase via specific intramolecular interactions. In the inactive state the kinase is in a compact conformation stabilized by the interaction between the SH3 domain and the linker between the SH2 and the kinase domains. The compact structure is further stabilized by the interaction between the SH2 domain and a phospho-tyrosine peptide in the short carboxy-terminal tail (Tyr527 in SRC). Both interactions, however, are sub-optimal and they only occur because the two interacting partners are covalently linked.

Kinase activation can be promoted in several ways. For instance, de-phosphorylation of Tyr527 leads to dissociation of the SH2 domain and, as a consequence, also of the SH3 domain. Once relieved from interaction with the peptide targets in *cis* the two domains can bind proteins containing appropriate motifs leading to kinase activation and target phosphorylation. In addition, since the regulatory interactions are designed to be weak they can be readily reversed when the SH modules encounter better ligands.

Mechanisms that are similar to the ones that we have described for soluble tyrosine kinases are also involved in controlling the activity of the SHP-2 phosphatase. Despite being a phosphatase, a class of proteins that are normally associated with the dampening of growth signals, SHP2 is a positive regulator of the RAS-MAPK pathway because it dephosphorylates and inactivates negative regulators of the pathway such as RASGAP and SPROUTY (Jarvis *et al.*, 2006; Montagner *et al.*, 2005). SHP2 contains two SH2 domains linked on the amino-terminal side to the tyrosine phosphatase domain. The phosphatase activity is normally kept in check because the SH2 domains fold back onto enzymatic domain and inactivate it. However, when adaptor proteins such as GAB1 are phosphorylated on tyrosines by growth signals, the SH2 domains dock onto the phosphorylated peptides thereby releasing the inhibitory interaction with the phosphatase domain. These mechanisms have been extensively characterized because, as described below, mutations that alter it cause severe human pathologies. A large number of activating or inactivating mutations in the SH2 or phosphatase domains have been characterized thus shedding light on this sophisticated regulatory mechanism (Tartaglia *et al.*, 2006).

SH Domains and Diseases

Given the important role played by SH domains in signal transduction, it is not surprising that mutations within these domains or their targets have been implicated in human diseases. For instance, loss-of-function mutation in the SH2 domain of Bruton tyrosine kinase causes some cases of X-linked agammaglobulinemia, which is associated with a deficiency in mature B cells and susceptibility to bacterial infection (Saffran *et al.*, 1994). A distinct inherited immune defect, X-linked lymphoproliferative syndrome, results from mutations in the SAP gene encoding a small protein that contains only one SH2 domain and a short carboxy-terminal tail (Sayos *et al.*, 1998). Noonan's syndrome, a developmental disorder associated with cardiac defects, facial dysmorphism, and skeletal abnormalities, can be caused by mutations in the amino-terminal SH2 domain of the SHP-2 phosphatase. The mutations presumably remove the inhibitory effect of the SH2 domain on the phosphatase domain (Tartaglia *et al.*, 2001). Somatic mutations that activate Shp-2 are also common in juvenile myelomonocytic leukemia (JMML) (Tartaglia *et al.*, 2003).

Although many proteins containing SH3 domains are 'disease proteins,' clear examples of disease mutations affecting an SH3 domain or its targets are not numerous. A homozygous mutation (A335V) in the MED25 gene has been linked to Charcot-Marie-Tooth neuropathy. MED25 is a

transcription cofactor but its physiological function in transcriptional regulation remains obscure. The A335V missense mutation is located in a proline-rich region which has high affinity for the ABL SH3 domains. The mutation causes a decrease in binding specificity leading to the promiscuous recognition of a broader range of SH3 domain proteins.

It should also be considered that naturally occurring polymorphisms could affect predisposition to disease by altering SH domain recognition specificity. For instance, a Trp-to-Cys substitution in the C-SH2 domain of ZAP-70 causes in the SKG strain of mice the development of chronic arthritis. This is caused by the inability of the polymorphic ZAP-70 protein to associate with the T cell receptor thus leading to impaired T-cell signaling and survival of auto-reactive T cells.

Another interesting example is that of a common polymorphism in the human p53 gene. A single nucleotide variant in the p53 gene is reflected in the presence of either an Arg or a Pro at position 72. This polymorphism has been linked to susceptibility to several types of cancers probably as a consequence of a markedly different apoptotic potential of the two p53 protein variants (Dumont *et al.*, 2003). The polymorphism affects the sequence of a proline-rich peptide that has the potential to bind to SH3 domains. It was recently shown that some SH3 domains show a differential preference for either of the polymorphic proteins. It was proposed that the differential capability to form these complexes is at the basis of the observed differential susceptibility to cancer (Panni *et al.*, 2015).

Conclusions

The versatility of SH3 and SH2 domains has been exploited in evolution to develop a dynamic network of protein interactions that supports cell organization and signal transduction. The impact of this network of interactions in cell physiology is not confined to specific functions but pervades most cellular pathways. By providing the molecular basis for the formation of a sensitive and dynamic network, SH3 and SH2 domains can exert a broad effect on cellular behavior. Perhaps most importantly, their characterization has built a framework for the discovery and analysis of additional families of interaction domains and has crystallized a new way of thinking about cellular organization.

The MAPK Signaling Cascades

R Seger and S Wexler, The Weizmann Institute of Science, Rehovot, Israel

Glossary

The mitogen-activated protein kinase (MAPK) Cascades are a central group of signaling pathways that respond to a variety of extracellular stimuli to induce and regulate cellular processes such as differentiation and proliferation.

They transmit their signals by sequential phosphorylation and activation of protein Ser/Thr kinases. Dysregulation of the cascade often results in pathologies such as cancer, diabetes, and other disorders.

General Overview

Cells respond to a large variety of extracellular signals through activation of transcription factors, which eventually induce the necessary cellular processes. These extracellular signals include signaling ligands such as hormones, growth factors, and cytokines, as well as environmental changes such as stress, changes in temperature, and osmotic pressure. Since most extracellular agents cannot cross the plasma membrane, in order for them to activate their corresponding genes, they use membranal receptors and intracellular signaling pathways to transmit the extracellular signals to target molecules either in the cytoplasm or in the nucleus. Such pathways are found in all organisms including bacteria, invertebrate, and ancient species and in many cases, they operate by sequential phosphorylations within protein kinase cascades. Most notable among them are the mitogen-activated protein kinase (MAPK) cascades that control fundamental cellular processes including proliferation, differentiation, motility, stress response, survival, and apoptosis (for recent reviews see: [Cargnello et al., 2012](#); [Keshet and Seger, 2010](#); [Plotnikov et al., 2011](#)).

The MAPK cascades are responsive to a wide variety of cues that transmit their signals via membranal receptors and other signaling components. These cascades funnel the information into either small G protein or adaptor proteins that are the immediate upstream activators of the cascades. The signals are then further transmitted through the cascade by three to five tiers of protein kinases. The kinases in each tier phosphorylate and activate the kinases in the downstream tier, to allow a rapid transmission of the signals to the cascade's targets. Three of the tiers; MAP3K, MAPKK, MAPK, are considered the core ones ([Figure 1](#)), while the upstream (MAP4K) or the downstream (MAPK-activated protein kinase; MAPKAPK) tiers are not always present. Kinases downstream of MAPKAPKs exist as well, but are not considered as part of the cascades. Each of the tiers is composed of several components, which are either distinct gene products, or alternatively spliced isoforms that often present distinct functions. The signals transmitted via the cascades are usually transient, with variable durations between minutes (transient) to hours (sustained), as determined by phosphatases and other regulatory proteins, as described below.

At present, four mammalian MAPK cascades are known and named according to their MAPK components: extracellular

signal-regulated kinase 1 and 2 (ERK1/2), c-Jun N-terminal kinase 1–3 (JNK), p38 α – δ (p38), and ERK5. Additional names for each of the cascades and their components are found in the literatures as well, and the full terminology can be found in ([Keshet and Seger, 2010](#)). Other kinases that share sequence similarities with the MAPKs have been identified as well (e.g., ERK3/4 and ERK7/8). However, the distinct mode of activation of these kinases suggests that they are not components of genuine MAPK cascades. Thus, about 70 genes are known today to encode for close to 200 distinct protein kinases that transmit signals within the cascades. Notably, phosphatases and other regulators bring the number of components of the entire MAPK system to well over 300. From the above, the MAPK and MAPKAPK components phosphorylate and modulate the activities of hundreds of substrates in various subcellular localizations and organelles ([Yoon and Seger, 2006](#)). Each of the cascades regulates several distinct, and sometime overlapping cellular processes. Generally, the ERK1/2 cascade plays a major role in proliferation and differentiation, JNK and p38 cascades are mainly stress-related, and the ERK5 cascade responds equally to both stress and mitogenic signals. Dependent on the cell and stimulation types, the cascades may regulate noncanonical and even opposing functions.

The ability of these seemingly simple, linear cascades to integrate a large number of extracellular stimuli, and regulate a variety of cellular processes has attracted much attention over the past two decades. Some of the mechanisms that are involved in the determination of signaling specificity are the intrinsic properties of the cascade, including: (1) the number of components in each tier of the cascade, (2) the unique selectivity of the MAP4K, MAP3K, and MAPKK components, (3) the progressive signal amplification, (4) the switch-like nature of the cascade, and (5) the rapid and transient nature of the transmitted signals. In addition, fine-tuning of the cascades' specificity is often achieved by: (1) interaction with other signaling cascades, (2) presence of many scaffolding proteins that bring components close together, (3) substrate competition, and (4) spatio-temporal regulation of the various components ([Shaul and Seger, 2007](#)). In this article, we cover the nature and functions of the four cascades, as well as their regulatory components. In addition we describe diseases that are induced and maintained by dysregulation of the cascades.

Figure 1 Schematic representation of the 4 MAPK signaling cascades.

Components of MAPK Cascades

The ERK1/2 Cascade

As all MAPK cascades, the ERK1/2 one is activated by many extracellular stimuli, including mainly growth factors, cytokines, and other mitogens (recent reviews are: [Matallanas et al., 2011](#); [Plotnikov et al., 2011](#); [Roskoski, 2012](#)). These stimuli usually transmit their signals by various membranal receptors that further activate a nucleotide exchange factor (SOS) and a small GTPase (Ras) at the plasma membrane. Other ways of Ras or Raf activation have been suggested as well, but those are much less frequent. No components are found in the MAP4K level of the cascade, and the main components at the MAP3K level are B-Raf and C-Raf, that are activated mainly by Ras-induced dimerization. A-Raf, KSR1/2 as well as MEKK1, Mos, and Cot1 are additional MAP3Ks, but those are activated by distinct mechanisms in restricted cell type- and stimulus-specific manners. The MAP3Ks then phosphorylate the MAPKKs MEK1 and MEK2 on the two serine residues within the activation motif Ser-Met-Ala-Asn-Ser in the kinases' activation loop. In turn, these MEKs phosphorylate ERK1 and ERK2 on the Tyr and Thr residues in the Tyr-Glu-Thr motif within their activation loop, inducing their full activation. Alternatively spliced forms of MEK1 (MEK1b) and ERK1 (ERK1c) have been described as well, and those seem to generate a unique

signaling route that regulates distinct processes than that of the MEK1/2-ERK1/2 routes ([Wortzel and Seger, 2011](#)). RSK1-3, MSK1/2, MNK1/2, and in some cases MAPKAPK3 and MK5, are the components at the MAPKAPK level, which are all phosphorylated and activated by ERK1/2 but can also be phosphorylated by other signaling kinases. The down-regulation of the cascade, which is mediated by several phosphatases, and the effect of the subcellular localization of the components on their activity are described below. Interestingly, while the activity of Rafs and MEK1/2 is restricted mainly to their downstream components, ERK1/2 and MAPKAPKs phosphorylate a large number of substrates, localized in various cellular compartments. The phosphorylation of all these substrates allows the cascade to induce and regulate a variety of cellular processes. Dysregulation of the cascade results in several diseases, including mainly cancer, as well as developmental and neurological disorders, as will be described below.

The p38 Cascade

The activity of this cascade is induced by various stress factors and ligands that operate via different receptors, including apoptosis-related receptors, GPCRs, and even receptor Tyr kinases (RTKs, reviewed in [Shiryaev and Moens, 2010](#)). In

addition, some of the physical stresses (e.g., heat and osmotic shock) are thought to operate in many cases via receptor-independent machinery that requires changes in membrane fluidity or other specialized signaling systems. Then, the signals are transmitted either by the small GTPases Rac and CDC42, or occasionally, activatory adaptor proteins. These two modes of upstream activators then stimulate protein kinases at the MAP3K tiers of the cascade. About 20 genes encode protein kinases at the MAP3K tier, and those are very similar to the MAP3Ks of the JNK cascade. They are activated mainly by small GTPases, but under some conditions, also by a few MAP4Ks, or even directly by adaptor proteins. This large number of MAP3Ks transmits the signals to a much smaller number of MAPKKs (mainly MKK3, MKK6), phosphorylating them on Ser and Thr residues at the typical Ser-Xaa-Ala-Xaa-Ser/Thr motif, in their activation loop. The next tier of the cascade is composed of products of four MAPK genes, including p38 α (SAPK2 α) and p38 β (SAPK2b) as well as p38 γ and δ . Importantly, p38 genes also express several alternatively spliced forms, bringing the number of isoforms of this group to ten, with molecular weights that vary between 32 and 54 kDa. These isoforms are all activated by phosphorylation of the Tyr and Thr residues in the Thr-Gly-Tyr motif in their activation loop. Unlike ERK1/2, p38 members can be localized both in the nucleus and/or in the cytosol, and their translocation upon stimulation seems to be bi-directional. The mechanism of nuclear translocation is similar to that of JNK (described below), while the export seems to be mediated by interaction with MAPKAPK2, which contains a nuclear export signal. Once these p38 members are activated, they either transmit the signal to the MAPKAPK level components (MAPKAPK2, MAPKAPK3, MNK1/2, MSK1/2, and MK5/PARK), or phosphorylate a large number of cytoplasmic and nuclear targets. The phosphorylation of all the substrates allows the cascade to induce and regulate a variety of cellular processes that include stress response, inflammation, immunological effects, and more. Dysregulation of the cascade results in several diseases, including inflammation-related diseases, neurological disorders, and diabetes, and even cancer.

The JNK Cascade

Similar the p38 cascade, the JNK cascade is responsive to stress/apoptosis-related receptors, receptor-independent physical stresses, GPCRs, and even RTKs (reviewed in [Bogoyevitch et al., 2010](#); [Haeusgen et al., 2011](#)). Those receptors, or receptor-independent stress-induced signals, further transmit the signals to adaptor proteins or small GTPases. The GTPases then are able to activate kinases in the MAP4K, and in some cases, MAP3K tiers of the JNK cascade. The kinases at the MAP4K tiers, include Ste20-like kinases, that can be shared with the p38 cascade, and can all phosphorylate and activate the kinases at the MAP3K tier. Again, most of the MAP3Ks are shared with those of the p38 cascade, although some of them have been reported only in the JNK cascade. Next, the activated MAP3Ks transmit the signals to kinases at the MAPKK level, which are mainly MKK4 and MKK7. Interestingly, MKK7 seems to express a particularly high number (~ 6) of alternatively spliced isoforms with distinct activities and those, together with alternative spliced isoforms of the MKK4, were

suggested to extend the specificity of the cascade. As the other MAPKKs, MKK4, and MKK7 are activated by phosphorylation of the typical Ser-Xaa-Ala-Xaa-Ser/Thr motif and are then able to transmit the signal further to the JNK level. Three genes (JNK1-3, SAPKs) encode the JNK proteins, which are translated from a total of ten JNK alternatively spliced transcripts. Interestingly, the spliced isoforms of JNK1 and JNK2 are either 46 kDa or ~ 54 kDa proteins, while JNK3 is mostly translated to a 52 kDa protein. The activation loop of JNK contains a Pro in the Xaa position (Thr-Pro-Tyr) and, as with the other MAPKs, both Thr and Tyr need to be phosphorylated to achieve activation. This cascade appears to be a major regulator of nuclear processes, specifically transcription, and the number of its cytoplasmic substrates is limited. Only one MAPKAPK, MAPKAPK3, is currently known to be a component of this MAPK cascade, indicating that most of the signaling is mediated by the JNK. These kinases usually associate with their targets and activate them to induce processes such as apoptosis, immunological effects, stress response and more. Again, dysregulation of the cascade was shown to lead to pathologies such as neurological disorders, diabetes, inflammation, and cancer.

The ERK5 Cascade

This cascade is activated by mitogens as well as stress stimuli, but is the least studied out of the four cascades (reviewed in [Roberts et al., 2009](#)). The mechanism of upstream activation of the cascade has not been fully elucidated, but may include activation of RTK/PTKs that either transmit their signals to the adaptor protein Lad1, or to WNK1, which acts as a MAP4K. These components activate the kinases in the MAP3K level, which are MEKK2/3 and possibly also TPL2 and MLTK. The MAP3K tier kinases then phosphorylate and activate the two alternative spliced MAPKK isoforms MEK5a (50 kDa) and MEK5b (40 kDa), which are both active kinases. As other MAPKKs, this phosphorylation occurs on the Ser-Xaa-Ala-Xaa-Thr activation motif of MEK5. The MEK5s then activate the MAPK, ERK5 by phosphorylating it on both Thr and Tyr residues within the sequence Thr-Glu-Tyr, which is very similar to that of ERK1/2. However, in spite of the similarity, ERK5 cannot be phosphorylated by MEK1/2, and MEK5 cannot phosphorylate ERK1/2. There is one gene that encodes ERK5, which is translated to one main protein of ~ 100 kDa, a size that gave this kinase its other name – big MAPK1 (BMK1). Upon stimulation, ERK5 phosphorylates the serum and glucocorticoid-activated kinase (SGK), which may serve as a MAPKAPK of this cascade. However, this does not seem to be the main substrate of the cascade, as several transcription factors have been identified as ERK5 substrates as well. Interestingly, unlike the other MAPKs, ERK5 was found to influence transcription by additional mechanisms, including direct protein–protein interactions with transcription factors, or intrinsic transcriptional activity that is mediated by its C-terminal noncatalytic half. These activities, allow ERK5 to mediate physiological processes including proliferation, angiogenesis, immunological processes, and stress responses. The cascade has also been implicated in cancer, and is likely to participate in other pathologies as well.

Regulation of the MAPK Cascades

The MAPK cascades are central signaling moieties, capable of communicating between many extracellular signals to various distinct and even opposing cellular processes. To avoid erroneous signaling, the activities of the MAPK cascades need to be well regulated. This is mediated by a set of regulatory proteins and processes that keep the level, duration, and localization of the signal under control, to ensure proper specificity and functioning, and avoid pathological outcomes. Some of the important proteins that directly regulate the cascades and their roles are described below.

Phosphatases

As mentioned above, all components of the MAPKK, MAPK, MAPKAPK and some of the MAP4K, and MAP3K tiers of the cascades are activated by phosphorylation. Inhibition of some of the components, as well as modulation of their activity often occurs by phosphorylation as well. Thus, phosphoprotein phosphatases are positioned to impact all aspects of MAPK cascade function (mainly negatively but in also positively; reviewed in Nunes-Xavier *et al.*, 2011; Yao and Seger, 2004). As of today, not much is known on the phosphatases that regulate the components at the upstream levels MAP4K, MAP3K, and MAPKK, but it is assumed that they are mostly regulated by the general Ser/Thr phosphatase PP2A. Another phosphatase that regulates MAP3K level components is PP5, which dephosphorylate activatory phosphorylations of ASK1 and Raf1, in order to inhibit their activity. On the other hand, the mechanism of MAPKs' dephosphorylation and inactivation is much better studied. Thus, dephosphorylation of either the pThr, pTyr or both in the activation loop of MAPKs causes a substantial decrease in activity. This is controlled by pTyr, pSer/Thr, or specific dual specificity phosphatases (DUSPs) known as MAPK phosphatases (MKPs). Interestingly, MKPs are usually not expressed in resting cells, and the initial MAPK regulation after stimulation is mediated by nonspecific phosphatases that are either pTyr or pSer/Thr phosphatases. The MKPs are then transcribed, and take over the dephosphorylation 45–75 min after stimulation.

This group of MKPs contains 11 proteins whose expression is different in various cell lines. In addition, each MKP member has different specificity toward the various MAPK. Some (e.g., MKP3) are specific to ERK1/2, while others are specific to JNK and p38, and MKP6 has similar specificity to ERK1/2, JNK, and p38. The specificity is mainly determined by the variant amino acids in the binding D-domain of MKPs. Not much is known about the MKPs that participate in the regulation of ERK5. Importantly, different MKPs are localized in different compartments, as some of them are exclusive to the nucleus, and some are found only in the cytoplasm. In addition, the phosphatases may strongly interact with their target MAPKs, to regulate not only their activity but also their subcellular localization. Thus, the distinct features of the MKPs enable differential regulation of MAPKs and their downstream processes.

Scaffold Proteins

Alongside mechanisms of cascade inhibition by phosphatases, scaffold proteins are thought to play a role in conferring

signaling specificity as well (reviewed in Pullikuth and Catling, 2007; Witzel *et al.*, 2012). These proteins allow formation of multicomponent complexes with two or more components of each of the cascades. Proteins that bind just one component are not considered as scaffolds, but may often serve as anchoring proteins to their interacting components, directing them to their right localization. The scaffold proteins have several functions, including: (1) facilitation of signaling rate by bringing distinct cascade components in close proximity to each other, (2) directing MAPK components to their proper subcellular localization, (3) upstream activators, (4) downstream targets, (5) various regulators, or even (6) stabilizing MAPK components due to protection from phosphatases and proteinases. These properties often determine signaling thresholds and allow regulation of the proper downstream cellular processes. Currently, the number of scaffold proteins known is limited, not exceeding ten for any cascade. However, it is likely this number is much higher.

One of the best-studied scaffolds of the ERK1/2 cascade is the KSR1, initially identified as a key component in the ERK signaling in *Drosophila melanogaster* and *Caenorhabditis elegans*. KSR1 has high homology to Raf1, and in some extreme cases can act as a MAP3K component by phosphorylating MEK1/2 (McKay *et al.*, 2011). However, it seems that the main function of this protein is the scaffolding of components of the cascade. Thus, in quiescent cells, KSR1 is associated with MEK1/2, but not with ERK1/2 or Rafs, and its activity is inhibited by the associated protein IMP1. Upon stimulation, the IMP1 is polyubiquitinated and degraded, which consequently induces regulatory changes in the protein. Consequently the KSR1 complex translocates to and interacts with the plasma membrane, recruiting an activated Raf1, which facilitates activation of MEK1/2. Simultaneously, ERK1/2 are recruited to the activated complex, activated, released from the complex and translocate to their sites of action. The mechanisms of action of most other scaffold proteins of the MAPK cascades seems to be less regulated than that of KSR1, as they undergo only limited numbers of regulatory phosphorylations.

Crosstalk with Other Signaling Cascades

Crosstalks and interplays between the distinct MAPK cascades and with other signaling components is an important regulatory mechanism in the determination of signaling specificity (reviewed in Fey *et al.*, 2012; Mendoza *et al.*, 2011). Such crosstalks can either affect the activity of components within the distinct MAPK cascades or impose combinatorial effects on targets downstream of the distinct cascades/pathways. For example, some of the cascades participate in negative upstream regulations of upstream components, such as the phosphorylation of EGFR by p38 that inhibits its activity toward the ERK1/2 cascade. The effects can occur within the various cascades, as exemplified by the phosphorylation of Ser298 of MEK1 by the PI3K-AKT-activated component PAK1. This phosphorylation induces further activation of the ERK1/2 cascade, demonstrating a positive influence of the PI3K/AKT pathway on the ERK1/2 cascade. An example of downstream crosstalk is the activation of IL2 gene promoter. This promoter requires binding of several transcription factors for its activation. Interestingly, some of the

factors lie downstream of distinct signaling cascades, including AP1 downstream of the JNK cascade, CREB downstream of PKA, or ERK1/2 cascades, and NFkB that is a representative of as yet another signaling pathway. Activation of several of these transcription factors upon stimulation is required for full promoter activity, while activity of just one of them causes a limited activation and may induce distinct physiological function. These mechanisms determine the signaling specificity by changing the output of the cascades at upstream components, various tiers, or downstream the MAPK signaling, to strongly affect the outcome of the MAPK signals.

Subcellular Localization of MAPK Components

Most components of the four MAPK cascades are localized in the cytoplasm of resting cells, and are translocated to the nucleus and other cellular compartments after stimulation (reviewed in Flores and Seger, 2013). In the ERK1/2 cascade the cytoplasmic localization is rapidly changing upon stimulation in various ways. The Rafs are recruited to the plasma membrane by the activated Ras, while MEK1/2 are rapidly shuttling in and out of the nucleus. Simultaneously, ERK1/2, as well as most of the MAPKAP, detach from their cytoplasmic anchors and translocate to the nucleus where they can stay for minutes to hours. The mechanism that allows these rapid changes of ERK1/2 and MEK1/2 translocation to the nucleus is phosphorylation-dependent binding to importin7. JNK and p38 also translocate to the nucleus in most cell types and upon many stimulations. Shortly after stimulation, these MAPKs detach from their cytoplasmic anchors, and interact with either importin7 or importin9 that further associate with importin3 to form a heterotrimer of importin7/9-importin3-MAPK that induces their translocation. ERK5 can be localized in the cytoplasm of resting cells and translocates to the nucleus upon stimulation as well. This is mainly mediated by a nuclear export signal, which is exposed in the inactive protein. However, unlike the other MAPKs, stimulation causes changes in conformation that hinder the export signal and expose canonical nuclear localization signals in the protein that interacts with importin- α/β to translocate the ERK5 to the nucleus. Interestingly, the various MAPK components can be localized in various cellular organelles and compartments as well. These localizations are mostly induced by stimulation-induced translocation, such as that of ERK1/2 to the mitochondria, or ERK1c to the Golgi. The mechanism of these translocations and their exact function is still obscured.

MAPK Signaling in Diseases

Since the MAPK cascades are such a central regulator of most if not all stimulated cellular processes, their dysregulation induces or is involved in many diseases (Kim and Choi, 2010). Below we discuss the involvement in cancer, developmental diseases and inflammation. However, the involvement of the cascade was noticed also in neurological disorders, diabetes, polycystic kidney disease, and others. Therefore, understanding the role of the MAPK cascades in conjunction with developing agents to circumvent these signaling-related diseases

may lead to novel strategies in the combat of a large number of diseases.

MAPK and Cancer

Dysregulation of the MAPK cascades is profoundly linked to cancer initiation and progression (reviewed in Lawrence *et al.*, 2008). Indeed, many known oncogenes encode proteins that participate in the activation or regulation of the MAPK cascades, and in particular the ERK1/2 one that is found activated in more than 85% of all tumors. Interestingly, this activation is not only mediated by upstream components of growth factor-related signaling, but often seen in cancer cells transformed by activated components of other signaling pathways. The most abundant oncogene upstream the ERK1/2 cascade is Ras, the various activating mutations of which account for about 33% of all cancer types. In addition, activating mutations of B/C-Raf, particularly B-Raf, act as driving oncogenes in about 5% of all cancers, but are particularly known as a cause for metastatic melanoma (~60%). Activating MEK1/2 mutations are the cause of about 1% of cancers, while no activating ERK1/2 mutations have been reported in cancer as yet. Being such a central cancer regulator, the ERK1/2 cascade is considered as a prominent therapeutic target. Indeed, several efficient Rafs and MEK1/2 inhibitors have been developed, and found to be efficient in combatting ERK1/2 cascade-addicted cancers, in particular B-Raf mutated metastatic melanoma. However, after several months of treatment, all patients develop resistance, indicating that more efficient inhibitors of the ERK1/2 cascade are required to better target the cascade in this cancer.

Other MAPK cascades have been reported to play a role in cancer, albeit their involvement does not seem to be as pronounced as the ERK1/2 cascade. Thus, activated JNK has been reported to phosphorylate and activate the transcription factor c-Jun, which participates in the induction of some cancer types. However, the deletion of *jnk* genes in various mouse cancer models have shown that in some cases JNK acts as a tumor suppressor. Similarly to JNK, dysregulation of the p38 cascade may have a dual role in cancer, as it can either mediate cell survival or cell death. Interestingly, its activation levels in patients were found to be mainly associated with advanced stages of the disease, but its role in improving prognosis has been reported as well. Finally, the ERK5 cascade has been reported to play an inducing role in cancer, and several inhibitors of ERK5 are currently used in an attempt to combat various cancer types.

MAPKs in Developmental Diseases

Germline mutations of components of the MAPK cascades, in particular, the ERK1/2 one induces various developmental diseases. The best-known group of such syndromes is the RASopathies (Rauen, 2013). This is a group of genetic diseases that include, among others, the Noonan, Costello and cardio-facio-cutaneous (CFC) syndromes. These congenital syndromes are characterized by a variety of defects that include craniofacial dysmorphism, cardiac malformations, cutaneous and skeletal defects, and more. Although the prevalence of each disease may vary significantly, it was recently estimated that the rate of all the syndromes is about 1 in 1000

individuals. This demarcates RASopathies as one of the largest group of neurodevelopmental and malformation syndromes, making them attractive targets for research and drug development. Mutations linked to RASopathies have been identified in many signaling components upstream the ERK1/2 cascade, mainly Ras, as well as several mutations in B/C-Raf and MEK1/2. However, the basic mechanisms underlying their onset, phenotypic consequences and chronic nature are not fully understood as yet.

Germline mutations have been shown to affect the JNK cascade as well. One such mutation is in the CYLD gene that has been described in the Brooke–Spiegler syndrome (BSS), which is the autosomal dominant predisposition to skin appendageal neoplasms. CYLD encodes a deubiquitinating (DUB) enzyme that negatively regulates the nuclear factor (NF)- κ B pathway and the JNK cascade. The mutants of CYLD stabilize and prolong the signaling through this cascade, most likely leading to the syndrome. Although no germline mutation has been reported for the p38 cascade, the activity of the latter was reported to be important in inducing a variety of syndromes including the skull abnormalities of Apert syndrome, Ataxia-telangiectasia and Rad3 (ATR)-related Seckel syndrome, which is associated with growth retardation and the Nakajo-Nishimura syndrome. ERK5 has not been reported to be involved in any genetic syndrome as yet.

MAPKs in Inflammation-Related Diseases

The various MAPK cascades, particularly the p38 one, play a role in the induction and regulation of various inflammation-related diseases (Kyriakis and Avruch, 2012). Thus, the p38 cascade has been implicated in bowel inflammation, including ulcerative colitis and Crohn's disease. Most of the effects of p38 in these diseases are mediated by MAPKAPK2 and activation of transcription factors. In addition, activation of p38 is involved in both asthma and COPD, which have chronic inflammation. In these diseases, the inflammatory responses are induced by cigarette smoke or others cues and results in the induction and release of proinflammatory cytokines/chemokines, and activation of inflammatory cell migration. These effects are all mediated by p38 in epithelial cells and macrophages, which also may underlie the corticosteroid insensitivity of severe asthma and COPD. Other inflammation-related diseases associated with the activation of p38 are degenerative diseases of the central nervous system, inflammation-related cancer, rheumatoid arthritis, multiple sclerosis, and more. Therefore, p38 inhibitors present an attractive treatment for these conditions. Currently p38 inhibitors have been disappointing in the treatment of patients, mainly due to their severe side effects such as liver toxicity, indicating that the use of these inhibitors might not be possible for most diseases. Aside from the p38, the JNK cascade is involved in a multitude of inflammation-related diseases, such as cancer, bowel diseases, neurological, and immunological conditions. However, the involvement of the JNK cascade in these diseases seems to be only secondary to that of p38. The ERK1/2 and ERK5 cascades seem to have a much smaller involvement in these diseases. Therefore, unlike the p38 inhibitors, the specific inhibitors of JNK, as well as ERK1/2 and ERK5 are currently not considered as beneficial drugs for inflammation-related diseases.

Brief History

Identification of the phosphatidylinositol 3'-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) pathway began in the mid-1980s. Since its discovery, interest among the scientific community and the quantity of research done in this pathway have been remarkable. Over the last 20 years, an enormous amount of evidence has demonstrated that PI3K/Akt/mTOR is a key signaling pathway involved in many physiological and pathophysiological processes.

In 1988, Cantley and colleagues identified a phosphatidylinositol (PtdIns) 3-kinase able to phosphorylate the 3-OH group of the inositol ring of PtdIns *in vitro*, yielding the PtdIns-3,4,5-trisphosphate (PtdIns3,4,5P3) (Whitman *et al.*, 1988).

Scientific attention to this pathway increased in 1991 through the development of a natural product with antifungal and immunosuppressive activity derived from the bacterium *Streptomyces hygroscopicus*. This compound, called rapamycin (or sirolimus), showed inhibitory activity against mTOR (Heitman *et al.*, 1991). Following studies discovered several functions of mTOR in higher eukaryotes, making this protein kinase to gain its central position in the signaling network that regulates cell growth and survival.

In 1991, three independent groups discovered a gene that encoded a serine/threonine (Ser/Thr) kinase, corresponding to Akt (Bellacosa *et al.*, 1991; Jones *et al.*, 1991; Coffey and Woodgett, 1991). Four years later, two independent groups highlighted that Akt was activated by growth factors in a PI3K-dependent manner (Burgering and Coffey, 1995; Franke *et al.*, 1995). The exact mechanism of this phospho-regulation was demonstrated in 1996 by Alessi and colleagues, who showed that activation of Akt required a double phosphorylation event on residues Thr 308 and Ser 473 (Alessi *et al.*, 1996). A year later, the same group identified a specific kinase that phosphorylated the Thr 308 residue, which they referred to as phosphoinositide-dependent kinase 1 (PDK1) (Alessi *et al.*, 1997). Then, in 2005, an mTOR complex 2 (mTORC2) was identified as the kinase complex that phosphorylates the other amino acidic residue necessary for full Akt activation (Sarbasov *et al.*, 2005).

PI3K

PI3Ks catalyze the phosphorylation of the 3-OH group of the inositol ring in one or more PtdIns lipid substrates. In turn, the PI3K products activate a number of cytoplasmic effectors, mostly by recruiting them to the plasma or other organelle membrane.

There are eight closely related mammalian PI3Ks, classified into three groups (I–III), based on their substrate preference and structural homology. All isoforms display the so-called PI3K core, consisting of C2, helical, and catalytic domains (Figure 1).

Class I PI3K

Class I PI3Ks preferentially phosphorylate PtdIns-4,5-bisphosphate (PtdIns4,5P2) to yield PtdIns3,4,5P3. PtdIns3,4,5P3 enables the recruitment to the plasma membrane and activation of downstream proteins that contain lipid-binding domains, such as the pleckstrin homolog (PH) domain and the phox homolog (PX) domain. Among others, both PDK1 and Akt are recruited to the plasma membrane by PtdIns3,4,5P3. Class I PI3Ks consist of two subgroups, depending on the receptor to which they match. Class IA PI3Ks are heterodimeric lipid enzymes comprising a p110 catalytic subunit (α , β , and δ , encoded by the *PIK3CA*, *PIK3CB*, and *PIK3CD* genes, respectively) and an adaptor/regulatory subunit (p85 α , p85 β , and p55 γ , encoded by *PIK3R1*, *PIK3R2*, and *PIK3R3* genes, respectively, or p55 α and p50 α , which are splice variants of *PIK3R1* gene). The single class IB PI3K comprises a p110 γ catalytic subunit which binds one of two related regulatory subunits, p101 and p84/p87 (Cantley, 2002).

Class IA PI3Ks can be activated by direct interaction with RTKs or GPCRs, whereas single class IB enzymes are exclusively activated by GPCRs. The regulatory subunits mediate membrane localization, receptor binding, and activation, whereas the catalytic subunit transfers phosphate groups to the PtdIns3,4,5P3. The different catalytic subunits display different patterns of expression and function. p110 α and p110 β PI3Ks are expressed in every mammalian cell type, whereas p110 γ and p110 δ PI3Ks are mainly expressed in leukocytes (So and Fruman, 2012).

Class II PI3K

Class II PI3Ks are monomers of high molecular mass that yield PtdIns-3-phosphate (PtdIns3P) and PtdIns3,4P2 from PtdIns and PtdIns-4-phosphate (PtdIns4P), respectively (Engelman *et al.*, 2006).

Mammal class II PI3K comprises three isoforms: PI3KC2 α , PI3KC2 β , and PI3KC2 γ . In humans, PI3KC2 α is expressed ubiquitously, and it is highly enriched in the heart, placenta, and ovary; PI3KC2 β is expressed in the placenta and thymus, whereas PI3KC2 γ is found in the liver, prostate, breast, and salivary glands (Falasca and Maffucci, 2012). All class II PI3K isoforms have a long C-terminus containing a PX and additional C2 domains (Vanhaesebroeck *et al.*, 2010). Class II PI3Ks do not interact with regulatory subunits, but the C- and N-terminus can mediate the regulation of their activation and enzymatic activity (Falasca and Maffucci, 2007).

Recently, it has been reported that class II PI3Ks are downstream targets of both activated RTKs and GPCRs (Falasca and Maffucci, 2012). PI3KC2 α and PI3KC2 β can be activated by a large number of growth factors, chemokines, and hormones such as insulin (Falasca and Maffucci, 2012). Moreover, class II PI3Ks generate distinct lipid products from

Figure 1 PI3K class domain structure: PI3Ks are divided into three classes based on their structural and biochemical features. All the PI3K isoforms have a catalytic domain PI3K core structure composed of a C2 domain, a helical domain, and a catalytic domain. C2, PKC homology 2 (-like) domain; CBS, clathrin-binding site; CC, coiled-coil domain; p85, p85-binding domain; PH, pleckstrin homolog domain; PRD, proline-rich domain; PtdIns, phosphatidylinositol; PtdIns4P, PtdIns-4-phosphate; PtdIns4,5P2, PtdIns-4,5-bisphosphate; RBD, ras-binding domain; Vps34, vacuolar protein sorting 34.

class I PI3Ks, and, by doing so, they activate different downstream effectors. For example, class II PI3Ks seem not to be involved in Akt activation.

Class III PI3K

The single class III isoform, termed vacuolar protein sorting 34 (Vps34), exclusively utilizes PtdIns as substrate to yield PtdIns3P and plays an important role in controlling vesicular protein sorting and autophagy. Vps34 is an endosomal kinase that can acquire multiple functions, forming a core complex with two other protein subunits: VPS15 and Beclin 1. The protein kinase VPS15 has been described as a regulatory protein, but its precise role in Vps34 regulation is still not completely defined (Backer, 2008). Beclin 1 has a central role in autophagy and participates in processes such as development, tumorigenesis, and neurodegeneration (Levine and Kroemer, 2008).

Akt

Akt, also termed protein kinase B (PKB), is the main downstream target of class I PI3Ks. Akt is a 57-kDa member of the AGC protein kinase family, which is the mammalian homolog of the *v-akt* oncogene. In mammals, there are three genes, located on different chromosomes, encoding for Akt1/α, Akt2/β, and Akt3/γ (Figure 2). Akt1 and Akt2 are present in every tissue (Hanada et al., 2004), whereas Akt3 is expressed in the

Figure 2 Akt isoform domain structure. All the Akt isoforms have a catalytic domain (kinase) in the central region of the molecule. The PH domain is located at the N-terminus and binds PtdIns3,4,5P3 t-membrane surfaces. The RD is at the C-terminus. The two phosphorylation sites necessary for Akt isoform activation are shown.

brain, kidney, and heart (Masure et al., 1999). Akt isoforms share a high degree of sequence homology in their catalytic domains, but diverge in other regions of the protein, i.e., the C-terminus regulatory domain (RD) and the N-terminus PH domain (Hanada et al., 2004). All three Akt isoforms bind to PtdIns3,4,5P3 through the PH domain, leading to

phosphorylation and activation of Akt itself (Scheid and Woodgett, 2003). The three isoforms contain similar phosphorylation sites: Thr 308 (Akt1)/Thr 309 (Akt2)/Thr 305 (Akt3) and Ser 473 (Akt1)/Ser 474 (Akt2)/Ser 472 (Akt3) (Hanada *et al.*, 2004). Threonine residues are within the catalytic domain, and their phosphorylation is mediated by PDK1 (Bayascas, 2010), whereas the serine residues are located in the RD and are phosphorylated by the mTORC2 or by other kinases, including integrin-linked kinase (ILK) or DNA-dependent protein kinase (DNA-PK) (Persad *et al.*, 2000; Figure 2). Full activation of Akt requires the phosphorylation of both residues; nevertheless, in the absence of Ser 473 phosphorylation, Thr 308 phospho-Akt can still phosphorylate some of its substrates (Guertin *et al.*, 2006). Once activated, Akt isoforms translocate to different subcellular compartments, including the endoplasmic reticulum, the mitochondria, the Golgi, and the nucleus, where they phosphorylate myriad downstream effectors regulating a variety of essential processes such as cell cycle progression, apoptosis, translation, glycolysis, and angiogenesis (Martelli *et al.*, 2012). Akt substrates often contain the phospho-Akt-substrate consensus motif (R-X-R-X-X-S/T-B), where X represents any amino acid and B represents bulky hydrophobic residues. Akt may either positively or negatively regulate the functions of its substrates, alter their subcellular localization, or modify their stability.

Akt enhances cell survival by inhibiting pro-apoptotic proteins and processes. Indeed, Akt negatively regulates the transcriptional activity of FoxO3a (Forkhead box O3), resulting in a decrease of expression of different pro-apoptotic genes such as caspase 9, caspase 3, Bim, Bad, Noxa, or Puma (You *et al.*, 2006). Moreover, Akt controls the activity of other transcription factors such as cyclic AMP response element-binding protein (CREB), the phosphorylation of which activates several anti-apoptotic genes such as Bcl-2 or Mcl-1 (Du and Montminy, 1998).

Other targets regulated by Akt and involved in the promotion of cell survival include the inhibitor of kappa B kinase- α (IKK α), which phosphorylates and activates the degradation of the inhibitory cofactor of NF- κ B (nuclear factor- κ B), I- κ B, inducing its degradation and the release of NF- κ B, which translocates to the nucleus, where it activates the transcription of pro-survival genes (Ozes *et al.*, 1999).

Another target of Akt is the murine double minute 2 (MDM2), an E3 ubiquitin ligase that negatively regulates p53 expression, the major cell death effector (Oren, 2003). Phosphorylation of MDM2 at Ser 166 and Ser 186 by Akt decreases MDM2 self-ubiquitination and renders the protein more stable. In this way, p53-mediated apoptosis is inhibited (Feng *et al.*, 2004).

Concerning the modulation of cell proliferation, Akt can phosphorylate and inactivate p21Waf1/Cip1 and p27Kip1, two members of the Cip/Kip family of cyclin-dependent kinase (CDK) inhibitors, which are required for cell cycle arrest in G₁.

Moreover, Akt can phosphorylate and then inhibit glycogen synthase kinase (GSK) 3 β . GSK3 β phosphorylates cyclin D1 at Thr 286 (Diehl *et al.*, 1998) and Myc at Thr 58 (Gregory *et al.*, 2003), leading to their nuclear export and degradation through a ubiquitin-mediated pathway. Consequently,

Akt-mediated GSK3 β inhibition results in cell cycle progression. Two other Akt substrates that play an important role in the regulation of cell cycle are Wee1 (Katayama *et al.*, 2005) and Myt1 (Okumura *et al.*, 2002). Both Wee1 and Myt1 are phosphorylated and inactivated by Akt, and these phosphorylative events facilitate cell cycle progression at the G₂/M phase transition.

As mentioned before, Akt also plays a key role in promoting cell growth, mainly through the activation of the mTOR complex 1 (mTORC1). Akt is therefore both an upstream activator of mTORC1 and a downstream effector of mTORC2. Akt phosphorylates 200-kDa tuberous sclerosis 2 (TSC2 or hamartin), leading to disruption of its interaction with tuberous sclerosis 1 (TSC1 or tuberlin) and to its degradation by the proteasome. TSC2 is a GTP-ase-activating protein (GAP) that associates with TSC1 to inactivate the small G protein Ras homolog enriched in the brain (Rheb), which accumulates in a GTP-bound state, which activates mTORC1. Phosphorylation by Akt negatively regulates the TSC1–TSC2 complex, leading to activation of mTOR (Inoki *et al.*, 2002). Moreover, the proline-rich Akt substrate of 40 kDa (PRAS40) inhibits mTORC1 activity. Phosphorylation by Akt represses the inhibitory function of PRAS40 on mTORC1 (Wang *et al.*, 2012).

mTOR

mTOR is a 289 kDa Ser/Thr kinase which belongs to the phosphatidylinositol kinase-related (PIKK) family (Memmott and Dennis, 2009) and is conserved throughout evolution. mTOR controls various cellular processes including cell cycle progression, survival, translation, metabolism, motility, autophagy, and aging. It collects input from upstream growth factor receptors, such as the PI3K/Akt, Ras/Raf/mitogen-activated protein kinase (MEK)/extracellular signal-regulated kinase (ERK), and liver kinase 1 (LKB1)/AMP-activated protein kinase (AMPK) pathways, in order to regulate several physiological events (Figure 3). In addition, it has recently been reported that mTORC1 also responds to inputs via the Hippo, WNT, and Notch signaling pathways (Shimobayashi and Hall, 2014).

mTOR is the catalytic subunit of two distinct complexes known as mTORC1 and mTORC2, which differ in partner proteins and substrate specificity. The two complexes have different functions: while mTORC1 positively controls cell survival, cell growth, and protein synthesis by promoting many anabolic processes and by limiting catabolic processes such as autophagy, mTORC2 regulates cytoskeletal rearrangement, cell survival, cell-cycle progression, and metabolism (Figure 3).

mTORC1 is composed of mTOR/regulatory-associated protein of mTOR (Raptor, a scaffolding protein)/mammalian Lethal-with-Sec-Thirteen 8 (mLST8)/PRAS40/FK-506-binding protein 38 (FKBP38)/DEP-domain-containing mTOR interacting protein (Deptor), and is sensitive to rapamycin and its derivatives (rapalogs). Different exogenous stimuli regulate mTORC1 activity, including growth factor signaling such as insulin and type I insulin-like growth factor (IGF-1), the energy state of the cell (that is, AMP levels), nutrient (e.g., amino

Figure 3 The PI3K/Akt/mTOR pathway activation. RTKs or GPCRs stimulate PI3K activity. Activated PI3K phosphorylates PtdIns4,5P2 to yield PtdIns3,4,5P3. PtdIns3,4,5P3 activity can be negatively regulated by PTEN and SHIP phosphatases. PtdIns3,4,5P3 recruits to the plasma membrane PDK1, which phosphorylates Akt at Thr 308. Full Akt activation requires Ser 473 phosphorylation by mTORC2. Akt activity can be negatively regulated by PP2A and PHLPP phosphatases. Active Akt inhibits TSC2 activity through direct phosphorylation. TSC2 is a GAP that functions in association with TSC1 to inactivate the small G protein Rheb. Akt-driven TSC1–TSC2 complex inactivation allows Rheb to accumulate in a GTP-bound state. Rheb-GTP then activates the protein kinase activity of mTORC1. mTORC1 targets S6K1, 4E-BP1, and S6RP. The phosphorylation of 4E-BP1 leads to the release of eIF4E, which interacts with eIF4G to activate translation initiation. However, other signaling cascades impinge on mTORC1, including GSK3 β , and the AMPK network which is sensitive to the ADP/ATP ratio. Arrows indicate activating events, while perpendicular lines indicate inhibitory events.

acids) and O₂ availability, and stress signals (Laplanche and Sabatini, 2009).

Regarding mTORC1 functions, protein synthesis is the best-characterized process controlled by this complex (Sengupta et al., 2010). When active, mTORC1 phosphorylates the translational regulator eukaryotic translation initiation factor 4E (eIF4E)-binding protein 1 (4E-BP1) and S6 kinase 1 (S6K1) (Thoreen et al., 2012). The phosphorylation of 4E-BP1 leads to the release of eIF4E, which interacts with eIF4G to activate translation initiation (Martelli et al., 2011).

Then, S6K1 phosphorylates the 40S ribosomal protein S6 (S6RP), leading to active translation, while 4E-BP1 interacts with the eukaryotic initiation factor 4B (eIF4B), which critically regulates cap-dependent translation (Browne and Proud, 2004). S6K1 activation also leads to increased mRNA

biogenesis, as well as translational initiation and elongation (Chauvin et al., 2014). S6K1 has several substrates, including insulin receptor substrate 1 (IRS1), which is upstream of mTORC1. Importantly, phosphorylation of IRS1 by S6K1 targets IRS1 for proteosomal degradation and thereby hampers the ability of growth factors (insulin, IGF-1) to signal downstream of RTKs (Laplanche and Sabatini, 2012). This results in inhibition of PI3K/Akt/mTOR activation, creating a negative feedback loop, which has an important role in the regulation of mTORC1.

Through the phosphorylation of various other targets, mTORC1 can trigger metabolic changes such as mitochondrial biogenesis, promotion of glycolysis, lipid biogenesis, and suppression of autophagy (Laplanche and Sabatini, 2009).

It has been reported that mTORC1 plays an important role in the maintenance of the mitochondrial oxidative function,

by regulating the interactions between the transcription factor yin-yang 1 (YY1) and the peroxisomal proliferator-activated receptor γ (PPAR γ) coactivator 1 (PGC-1), thereby preventing the coactivation of YY1 (Cunningham *et al.*, 2007).

Recently, an involvement of mTORC1 in lipid synthesis has been described. Lipid synthesis is required for proliferating cells to generate membranes, acting through the sterol regulatory element-binding protein 1/2 (SREBP1/SREBP2), which are transcription factors of lipogenic genes, as well as through PPAR γ , which are necessary and sufficient for the differentiation of preadipocytes and lipid accumulation (Laplane and Sabatini, 2012).

Furthermore, mTORC1 suppresses autophagy, a complex catabolic process that sustains cellular metabolism through recycling of cellular components during growth-unfavorable conditions. mTORC1, under stress conditions, transduces anti-autophagic signals by binding to the UNC51-like kinase (ULK) multi-protein complex, which is essential for the initial formation of the phagophore. mTORC1 can negatively regulate autophagy directly through phosphorylation of both ULK1, at Ser 638 and Ser 757, and ATG13 (Ganley *et al.*, 2009), or indirectly via TSC2 (Kim *et al.*, 2011).

mTORC2 is composed of mTOR/rapamycin-insensitive companion of mTOR (Rictor)/mLST8/stress-activated protein kinase-interacting protein 1 (SIN1)/protein observed with Rictor (Protor)/Deptor. mTORC2 is mainly activated by growth factors and insulin and seems to be insensitive to amino acids. mTORC2 regulates different downstream AGC kinases such as Akt, serum-, and glucocorticoid-stimulated kinase (SGK) and protein kinases C (PKCs). Moreover, mTORC2 controls cellular survival and spatial control of cell growth via cytoskeleton regulation, by stimulating of actin fibers, paxillin, RhoA, Rac1, and PKC α (Oh and Jacinto, 2011).

Regulation of the PI3K/Akt/mTOR Pathway

The regulation of the PI3K/Akt/mTOR axis is extremely complex, due to the existence of a very intricate network of negative feedback loops.

mTORC1 can regulate the PI3K/Akt/mTOR pathway at different levels. First, mTORC1 elicits a negative feedback that antagonizes the formation of mTORC2, thus lowering Akt activity (Sarbasov *et al.*, 2005). Therefore, inhibition of mTORC1 may result in Akt hyperactivation. Furthermore, when active, mTORC1 phosphorylates S6K1, which can induce the proteosomal degradation of IRS1, by phosphorylating it at multiple sites, resulting in a decrease of PI3K/Akt/mTORC1 activation (Bhaskar and Hay, 2007). mTORC1 can also down-regulate IRS2 expression by enhancing its proteosomal degradation (Bhaskar and Hay, 2007).

Furthermore, the existence of a rapamycin-sensitive, mTORC1/S6K1-mediated phosphorylation of Rictor on Thr 1135 has been documented. This phosphorylative event exerted a negative regulatory effect on the mTORC2-dependent phosphorylation of Akt *in vivo* (Boulbes *et al.*, 2010).

Moreover, it has been demonstrated that FoxO1, in a TSC2-dependent way, can activate AMPK, which in turn directly inhibits mTORC1 and activates Akt, suppressing the S6K1 feedback (Chen *et al.*, 2010). TSC1/2, in addition to its role in
